INDEX TO VOLUME III.

The asterisk (*) denotes that the subject is illustrated.

<i>Abies balsamea</i>	494
— brachyphylla.....	255
— bracteata.....	332
— Cilicica.....	111
— Eichleri.....	434
— grandis.....	494
— insignis.....	308
— Nordmanniana.....	308
— subalpina.....	162
— Tsuga.....	430
<i>Abrus precatorius</i>	42
<i>Abutilons</i> , bud varieties in.....	300
<i>Acacia Arabica</i>	124
— dealbata.....	123, 151
— decurrens.....	123
— Farnesiana.....	151, 344, 362
— flexicaulis.....	344, 362
— melanoxylon.....	123
<i>Acalypha marginata</i>	68
— Wilkesiana.....	68
<i>Acanthaceae</i>	252
<i>Acanthopanax ricinifolia</i>	12
<i>Acanthorrhiza stauracantha</i>	480
<i>Acer circinatum</i>	292
— Colchicum rubrum.....	405
— Ginnala.....	476, 520
— Pennsylvanicum.....	54, 144
— polymorphum.....	75
— saccharinum.....	36
<i>Achillea argentea</i>	243
— Millefolium.....	255
— ptarmica.....	397
— serrata.....	408, 504
— serrata plena.....	397
— tomentosa.....	337
<i>Achilleas</i> , propagating.....	484
<i>Acneta densa</i>	572
<i>Aconitum autumnale</i>	288
<i>Aconitum Loddigesii</i>	175
<i>Actaea spicata</i>	603
<i>Actinella acaulis</i>	559
<i>Adiantum versicolor</i>	404
<i>Adiantum alatum</i>	586
— aneense.....	397
— Belagerii.....	586
— cardiophloea.....	384
— cicutarium.....	586
— cuneatum.....	286
— curvatum.....	397
— digitatum.....	396
— Fabianum.....	586
— Farleyense.....	384
— fœniculaceum.....	586
— formosum.....	383, 586
— gracilimum.....	286
— hispidulum.....	286
— intermedium.....	396
— longissimum.....	586
— pedatum.....	631
— Peruvianum.....	383
— Sanctæ Catherine.....	384
— serra.....	586
— tenerum.....	384
— tetraphyllum gracile.....	396
— trapeziforme.....	396
— villosum.....	384
— viviparum.....	586
— Wiegandii.....	286
— Wilesianum.....	396
— Williamsii.....	286
<i>Adiantums</i> , a few strong-growing.....	383, 399
<i>Adirondack forests</i> , destruction of.....	507
— League Club.....	520
<i>Adirondacks</i> , legislation for the.....	49, 121, 209, 282
— the, thirty-six years ago.....	618
<i>Adlumia Amurensis</i>	499
— cirrhosa.....	310, 410, 542
<i>Adonis vernalis</i>	467
<i>Æcidium Sambuci</i>	346
<i>Ærides Angustianum</i>	344
— J'Ansoni.....	380, 428
— Lawrencei.....	550
— Roebelenii.....	92
— Sanderianum.....	550
— Savageanum.....	5
<i>Æsculus flava</i>	368
— Parryi.....	356*

<i>Æsculus Pavia</i>	295
<i>Aganisia cœrulea</i>	550

Organized Protection for Parks.

THE proposal to seize a portion of Central Park as a site for some of the exhibition buildings of the World's Fair has been discussed in these columns more than once, but we refer to it again, because it is a matter of much more than local interest. As an admirable example of pastoral scenery in the heart of a great city, and as the first work with such a motive ever designed for such a situation, Central Park is in a sense a national possession and is regarded with pride by the entire country. At all events, the proposed invasion is a representative case, and as such should command the attention of all those who have an intelligent appreciation of the value of public parks in cities and who wish to protect them from encroachment and spoliation. The pressure of the expanding city is felt on every foot of the boundary of every open space in New York, and the most powerful interests are constantly pushing to gain a foothold for some special purpose on the land devoted to public use. This situation is repeated in each of our rapidly growing cities, and unless the resistance to these constant assaults is unrelenting and determined, we may expect to see many other urban parks share the fate of our own City Hall Park, and gradually disappear, or else become perverted to purposes foreign to their design and destructive of their highest usefulness.

It is not our purpose to repeat the reasons for preserving park areas, and especially for protecting those whose beauty and value will continue to increase for generations to come. But taking it for granted that a park is worth preserving, it should be remembered that it is only safe when public sentiment is intelligently and actively interested in its behalf. And since the attacking forces may be swift and strong, public opinion needs to be organized for expression and always ready in an emergency. It is known to every one who is familiar with the history of Central Park that the newspapers of the city have saved it from ruin more than once, when even its legally constituted custodians were eager to surrender it; and when the question of appropriating a portion of the park for the World's Fair was under discussion, the unanimity of the press, outside of the daily papers, was surprising. Journals in the special fields

of architecture, art and engineering, and the leading literary, pictorial and religious weeklies, with scarcely an exception, took a firm stand against the invasion. It may be that this aid can always be counted on; but the real danger comes when the sober sense of the community is prostrated before a sudden gust of enthusiasm for some dazzling enterprise, whose right to occupy and possess the park is insisted upon as superior to that of the people or of their descendants.

It is plainly the part of wisdom to make preparation for such emergencies, and one assurance of safety against these sudden assaults might be found in a permanent association organized for the special purpose of protecting the parks from injury. True, there is a Board of Commissioners whose official duty it is to care for them. But this Board may need the positive support of public opinion, just as the Park Department in this city requires support to-day; and the time may come when the authorized guardians of the parks are their most dangerous enemies. In either case a voluntary association of public-spirited citizens, whose names would command respect and who would look at every question affecting the parks from the people's side, and not from the point of view selected by some special interest, could not fail to exert a wholesome influence. Such an organization, with a permanent Secretary, and, when needed, a paid staff, would be prepared not only to give timely warning of coming danger, but to give opportunity for public opinion to find effective expression. An association in New York, for instance, charged with the duty, could have at Albany when the legislative session begins, protests against any change in the law forbidding exhibitions in Central Park, from the associated architects of the city, from the artists, the physicians, the clergymen, and from citizens of every calling. The sum of the matter is that all parks in our cities are exposed to attacks, which are the more dangerous because many of them come from combinations of worthy people, organized for worthy purposes. The ultimate safety of these pleasure-grounds can be assured only by an enlightened and alert public sentiment; whether some systematic plan for helping the public will to find expression is not needed now to meet well organized attacks against them is a question worth considering by the friends of public parks in all our cities.

The volume of the final reports of the tenth census, for which the largest demand has been made at the Department of the Interior, is the ninth, which is devoted to the forests and forest-resources of the United States, and the edition is now nearly exhausted. This fact seems to indicate that the American forests, which ten years ago created no real interest except among persons engaged actively in destroying them, have now become a matter of general concern with thoughtful persons in all classes of society. Ten years ago little was known, actually, of the extent or composition of our forests. The conditions essential to the distribution and development of our most valuable trees, and the character even of the material produced by many of them, had not been determined; and the productive capacity of the forests of the country, if any one thought about it at all, was considered inexhaustible. Now it is known where our forests are, at least, and how they are composed, what they produce and how long they may be expected to remain productive; and there is hardly a newspaper in the United States which does not contain, from time to time, valuable information about forests and forestry. Commissions have been appointed in a dozen states to collect and disseminate knowledge about forests, and the interest in the subject is increasing on all sides. This result has been brought about by the hard and untiring work of a few conscientious investigators. Their work has not been thrown away if it has prepared the way by this general dissemination of knowledge for the gradual introduction into the United States of systems of forest-management which, when they are adopted, will

relieve us from the stigma of standing alone among civilized nations in disregarding the value of the forest as the foundation of all permanent national prosperity.

If the forests of this country should perish, agriculture and the arts would perish with them. Material development would be arrested and poverty would replace prosperity from one end of the land to the other.

The Deciduous Cypress.

THE view of a Cypress-swamp in southern Indiana, which appears upon page 7 of this issue, will serve to give an idea of the appearance of the Deciduous Cypress as it is found growing toward the northern limits of its distribution, where it does not attain to the vast size which characterizes this tree further south, and especially in Mexico. But in Indiana, even the Cypress, if not as large as it is often seen south of the Ohio River, is still a tree of respectable size; and Mr. Robert Ridgway, of the Smithsonian Institution, who has sent us the photograph from which our illustration has been made, has measured trees in the swamps near the mouth of White River nearly 150 feet high, and trunks eight feet through above their swollen and buttressed bases. Trunks twelve or fourteen feet through have been seen in the southern States; and a few years ago it was not difficult to find them ten feet in diameter in the great swamps bordering the lower Mississippi and some of the other rivers of the Gulf States.

The Deciduous Cypress first appears in the Atlantic States in the lower portion of Delaware; thence it extends, generally near the coast, to southern Florida and through the Gulf States and the Valley of the Mississippi to the banks of the lower Ohio. This species, or a related one hardly to be distinguished from it, reaches far south into Mexico, where it attains enormous size and an individual existence lasting through centuries.

The Cypress in the United States grows always in water or on low, flat land adjacent to rivers or great shallow lakes, often covered with water during weeks or months at a time. That part of the trunk which is covered with water, or which is liable to be, is greatly enlarged and strengthened by huge, often hollow, buttresses, which project out in all directions. Each of these buttresses terminates in a large branching root, which extends out to a great distance, sending down stout anchor-roots deep into the ground, and with many lateral roots, from which spring the "knees" peculiar to this tree. The trunk, covered with furrowed, dark red bark, shoots up perfectly straight from its enlarged base, forming a tapering column eighty or ninety feet high, when it divides into a number of long, stout, horizontal branches, which form the wide, flat top, which is hung generally with the long stems of the Southern Moss (*Tillandsia usneoides*). Naturalists have puzzled over the Cypress knees and the purpose of this development, almost ever since the tree was discovered; and they have formed the subject of many essays. The knees first appear, often close together, as small tubercles on the upper side of the roots. They grow rapidly until they attain a height of from two to ten feet, or have pushed well above the water-level, when they cease growing upward, and increase in diameter. The upward growth is very rapid, and the bark covering the growing top is soft and spongy. There are various facts which seem to indicate that the service which these peculiar growths perform for the tree is to bring air to the roots, otherwise cut off by the water which covers them during a considerable portion of the year, from all connection with the atmosphere. This is the view of Professor N. S. Shaler, who has made a careful study of this tree, and who finds "that it is not unreasonable to conjecture that this function of the knees is in some way connected with the aëration of the sap."* His facts are "the failure of the knees to develop when the trees have grown on high ground; the development of the knees above the permanent water-level, and to a height varying with that level; and finally, the destruction of the trees whenever the level of permanent water rises above the top of the knees."† These views are confirmed by a more recent paper,‡ published by Mr. W. P. Wilson, in the Proceedings of the Philadelphia Academy, in which it is shown that other plants besides the Cypress, which grow habitually with roots covered with water—the Water Gum (*Nyssa silvatica*, var. *aquatica*), *Avicennia nitida* and *Pinus serotina*—develop similar root-processes; and what is still more suggestive, Mr.

Wilson has induced plants of Indian Corn to send roots above the surface of the soil by keeping it continually saturated with water.

There is another point, and an important one, in the life history of our Cypress, which has never been satisfactorily explained. The great masses of this tree and the largest individuals are found in swamps or in shallow ponds, which are never dry except during periods of exceptional drought, and where the water is several feet deep at the time the seed would germinate. How did these great trees begin their existence, which may have extended through centuries, and how did the seed from which they spring find an inch of dry ground to attach itself to? The evidence points to a larger quantity of water in all our rivers and swamps five hundred or a thousand years ago than at present, and it is certainly improbable that the great swamps of the southern states could have been dry at any time during the period that the Cypress has occupied its present territory. Seedlings do not now appear among the old trees growing in the wet swamps and ponds, and they are only found on the margins of swamps in comparatively dry ground. Professor Shaler's hypothesis that the great trees in deep water have grown from branches blown down from neighboring trees, and rooted in the mud, is hardly consistent with the manner of growth of coniferous trees, and some other solution of this phenomenon must be sought for.

The vast size and beauty of this tree, the great age to which it attains, the peculiarities of its growth, the value of the material which it supplies to man, and its commercial importance, are not more interesting than its history. Like its near relatives, the California Sequoias, *Taxodium*, represented now only by our southern tree of comparatively restricted range, and by a very similar species in China (*Glyptostrobus* or *Taxodium Sinense*), once played a much more important part in covering the surface of the northern hemisphere than it does in these days. For in latest tertiary times just preceding the glaciation of the northern hemisphere, our *Taxodium*, with Sequoias and various Ginkgos, grew in Greenland and in Spitzbergen, and then was widely spread through North America and Europe, where grew, too, a *Glyptostrobus* almost identical with the existing Chinese tree. The coming of the ice drove all these trees out of Europe entirely, and forced *Taxodium* into what is now our southern states, and on to the highlands of Mexico, where the survivors of this once mighty race, barely altered by their new environments, now find their only abiding place.

The Art of Gardening—An Historical Sketch.

XVI.—Mediæval Europe.

WHEN barbarian hordes from beyond the Rhine began to spread over the lands where Rome had ruled, first the isolated country-seat and then the suburban villa was abandoned, all classes seeking refuge within the walls of towns. Once deprived of constant skillful attention, the gardens of the Romans gradually decayed. "The walks were overgrown first with grass, then with bushes and then with forest trees, and on the former beds and playgrounds the shepherd pastured his flocks."* Yet we must not think of the ruin as immediate or complete. Even a Goth or a Vandal could appreciate the charms of an Italian country home, if he lacked the power to preserve them in perfection. We read of Theodoric restoring and improving the imperial gardens at Ravenna, and of Totila (strange conjunction!) inhabiting Hadrian's villa at Tivoli; and a story is told of some Christianized Goth who diversified his clipped Box-trees by causing some of them to be cut into the shape of the cross. When, in the sixth century, the troops of Belisarius entered Grasse, about fifty miles from Carthage, they found a palace of the Vandal kings and countless villas, surrounded by gardens "which might deserve the Persian name of Paradise," and which Procopius declared were finer than any he had seen in the East or the West.† Of course they were an inheritance from the Roman colonists whom the Vandals had dispossessed three centuries before. Even at the dawn of the Renaissance there were traces of ancient gardens still to be found in various parts of Italy and southern France which, together with the descriptions that Pliny and others had bequeathed, greatly influenced the re-birth of the art of ornamental gardening.

In the north, however, Roman relics perished more quickly and there was small effort made to replace them. Almost the only gardeners of the early mediæval world were the monks, who, within the walls of their great establishments, cultivated

* Notes on *Taxodium distichum* in *Men. Mus. Comparative Zoölogy*, xvi., Nos. 1 and 2.

† Gibbon: "Decline and Fall of the Roman Empire;" chap. xli.

fruit-trees and trellised vines on an extensive scale, had flower gardens with intersecting walks and rectangular beds, and brought the water they needed in canals of masonry or wood.* Sometimes a special part of the monastic garden was set apart for medicinal herbs, and here we see the germ of the scientific botanical collections of later days. The Benedictines were particularly devoted to all works of cultivation, and even into England, where the heathen Angles and Saxons had obliterated even the memory of the horticulturist from imperial Rome, these new emissaries of the now papal city soon brought again a knowledge of useful plants and flowers.

The mediæval burgher had at first but little chance to develop a love for gardens, yet as soon as he attained to any degree of comfort—in the twelfth and thirteenth centuries—his house usually had a small garden in the rear. The noble, during the more unsettled centuries when he was forced to be constantly on the watch for enemies, perched on a hill-top or sequestered in an inaccessible glen, had no garden except his court-yard, where, in Germany at least, a great Oak or Linden usually rose among the little flower-beds. The crusades introduced him to some acquaintance with exotic plants, and then Oleanders, Pomegranates and other ornamental shrubs in pots often stood beside his door. In France the late-mediæval chateau always had a garden with a turfed lawn, vine-clad arbors, parterres chiefly filled with Roses, an orchard, a vineyard and a fountain if possible.† In England, a writer of the twelfth century, Alexander Neckham, describing a baronial garden, corroborates the belief that “at the outset it corresponded to our kitchen-garden,” yet suggests “a certain share of taste in arranging the herbs, plants and fruit-trees.”‡ When Fitzstephen’s “Chronicle” says of London, at the same period: “Adjoining to the buildings of that city all round lie the gardens of the citizens who dwell in the suburbs, which are well furnished with trees, are spacious and beautiful,” we can understand nothing more than kitchen-gardens; and even these must have been devoted chiefly to fruits, tubers and herbs, for scarcely any green vegetables were consumed in England before the time of Henry VIII.

Even kings and princes long lived between walls, and prided themselves upon gardens which to-day would seem ludicrously small and poor. They make a great feature in the writings of the time, but seldom were more than walled enclosures, with clipped trees forming arbors and connecting covered walks, a fountain or canal, formal flower-beds, and stiff little shrubberies. Childebart, in the sixth century, laid out a Rose-garden for his wife in Paris, probably near the present Hotel de Cluny, where the ruins of Roman baths still remain,§ built terraces and grafted his fruit-trees with his own hand. Charlemagne is considered the first real patron of horticulture, and full lists are still extant of the plants with which he adorned his palace-gardens at Ingelheim and Aix-la-Chapelle. But it is impossible to gain an idea of his work considered from the point of view of art, nor can we discover just what was the aspect of the place in the great Dominican convent at Cologne, where, centuries later (in the month of January, 1247), Albertus Magnus entertained the King of Holland “in pleasant warmth amid fruit-trees and blossoming plants.”¶ Some sort of forcing-house is, of course, implied, and therefore the great schoolman is often cited as the restorer of the long-forgotten art of cultivation under glass. Indeed, his skill in this direction is said to have been one of the reasons why he was accused of witchcraft.

In this same thirteenth century St. Louis laid out the end of an island in the Seine at Paris as a garden; and Frederick II. of Germany, wishing to reproduce the delights of his Sicilian home, constructed a garden at Nuremberg which was compared to the hanging-gardens of Babylon because it had terraces supported by arches. Another Parisian garden, large for the time, lay between the Louvre and the church of St. Germain des Prés.|| But more remarkable was the garden of the Hotel St. Paul, which covered twenty *arpents* of ground, and which Charles V. filled with all manner of living curiosities, especially prizing his cages of parrots. A labyrinth of clipped trees was its chief feature, but when Paris fell into the

hands of the English this was removed by the Duke of Bedford, and the spot planted with Elms. In all descriptions of similar spots we read of cages for animals, aviaries, fish-ponds and arbors, which by their names recall the features of a Roman villa-garden, but were very different in size and artistic value. How small and simple were the finest of the early northern pleasure-grounds may be read in the enthusiasm of the Crusaders over every garden which they saw in Asia, or even in the south of Europe. Nor did later centuries improve upon them much until the Italian Renaissance spread its influence over the whole of Europe. Even in the fifteenth century, a garden which Philip the Good, of Burgundy, laid out at Hesdin, in Flanders, gained its fame from the puerile surprises and mechanical toys with which it delighted the fantastic taste of the time. Of course, however, shade-trees as well as the features already mentioned were always prized, and an old historian mentions the pleasure he felt at seeing 5,913 Elms brought with their roots by water to Paris.* The early kings of France had country-houses in the vicinity of their capital, but sought them for the pleasures of the chase, not of the garden.

The true successors of the Roman artists during the mediæval period were first, the builders of the new Rome which rose beside the Bosphorus, and then the Moslem conquerors who, between the seventh and the fourteenth centuries, spread themselves over so vast a portion of the Mediterranean lands.

Constantine and his immediate successors imitated in their capital not only the buildings but the pleasure-grounds which they had left beside the Tiber, and Justinian, in the sixth century, greatly improved upon their work. Many of the twenty-five churches which he built in the city and its suburbs were placed amid beautiful groves, and on the Asiatic shore, near Chalcedon, he laid out splendid gardens around the summer residence of Theodora, which were praised by the poets of the age for “their rare alliance of nature and art.”†

By the ninth century generations of luxurious emperors had given the great palace at Constantinople a size, a splendor and a variety which the occidental imagination can hardly realize. Constantine Porphyrogenitus himself wrote a description of it. We cannot restore its arrangement from his words, but we learn that it was a vast aggregate of buildings and gardens with colonnades, avenues, fountains, basins and parterres; that one garden, laid out in terraces, overlooked a great race-course; and that another, the central feature of which was the famous banqueting-hall called the “Chrysotriclinium,” contained seven peristyles and eight court-yards planted with Plane-trees.

M. G. Van Rensselaer.

New York.

Holiday Notes in Southern France and Northern Italy.—IX.

IT is a difficult task to write an account of such a garden as that of Mr. Hanbury. I find a pocketbook half full of notes taken there, and I have been making selections from these and again going through these selections a second or third time in order to keep my account within reasonable bounds. Readers may form some idea of the extent of the collections at La Mortola when it is stated that the “Alphabetical Catalogue of Plants growing in the open air in the garden of Thomas Hanbury, F.L.S.,” occupies sixty quarto pages; at the end of this catalogue the plants are arranged geographically—that is to say, alphabetically under each country. A mere glance through this portion shows at once how much each part of the world contributes to the gardens of the Palazzo Orenco. A Systematic Catalogue—published like the last in 1889—has the plants arranged in families, and so without trouble the relative importance—in numbers—of the various natural orders can be readily ascertained. Both lists give, after name of plant, references to either descriptions or figure, the time of flowering at La Mortola and the native country of the species.

Winter or early spring is the best time to see this garden; then, I have no doubt, the words of Mr. Hanbury’s gardeners, Signori Villa and Verri—both men who not only know plants, but love them—would be doubly true. Whilst wandering from one surprise to another my companion and myself frequently expressed our astonishment and admiration, until at last our courteous conductors remarked, “At this season the place is not such great things, but come in winter or spring and you would at once call it an earthly paradise.” In its issue of February 20th, 1886, the *Gardeners’ Chronicle* contains a list of plants in flower on February 2d at La Mortola; the list contained the names of upward of five hundred species.

* Sauval, quoted by André: “L’art des Jardins.”

† Gibbon.

* Viollet-le-Duc. “Dictionnaire de l’architecture.—Jardins.”

† Viollet-le-Duc.

‡ W. C. Hazlitt: “Gleanings in Old Garden Literature.”

§ André: “L’art des Jardins.”

¶ August Demmin, in “Studien ueber die bildende Kuenste und Kunsthandwerke,” says that the banqueting-hall was encircled by fruit-trees, that the tables were decorated with Roses, and Almond and Vine-branches, and that a Vine-arbor spread above the seat of the King.

|| In Alphand’s “L’art des Jardins” there is a picture taken from a fourteenth-century tapestry, which represents the regular rows of trees with which this garden was planted, and a parterre in which intricate patterns were constructed with low clipped Box-hedges.

A few data summarized from the catalogues mentioned will give some idea of the extent and interest of Mr. Hanbury's collections. There are fifty-one Agaves, sixty-nine Opuntias, thirty-nine Cereus, as many Mamillarias, forty Aloes, twenty-seven Stapelias and nearly a hundred Mesembryanthemums. To go on counting would be a somewhat tedious task for the writer, and the results of his efforts, if published to any extent, would probably prove as tedious to the readers of GARDEN AND FOREST; I therefore drop statistics with the remark that Acacia occupies a page and a half and Solanum nearly a page of the catalogue.

Of course all the Palms mentioned in previous series of notes, and many others besides, are to be seen at La Mortola, but the general collections of plants are too vast to allow space for large masses of each species. The most attractive member of the genus Phoenix—I am speaking of those cultivated in the open ground along the Riviera—is *P. Canariensis*; it is a quick grower, and is now grown in enormous numbers. Instead of having somewhat scattered glaucous pinnæ and rather stiff habit like the common Date Palm, it has more numerous glossy bright green pinnæ and a graceful habit. There seems to have been some doubt always as to the origin of this species until Dr. Christ, of Basle, who studied some year or two ago the flora of the Canary Islands on the spot, found localities in which truly wild colonies of the Phoenix were growing; other evidence of an historical nature collected by Dr. Christ, and his companion, Dr. Bolle, furnishes additional proof that this handsome Palm is really a native of the Canary Islands. Altogether forty-four Palm-names figure in Mr. Hanbury's catalogue—some of these, however, will have to be reduced when the plants flower and fruit.

I select a small proportion of the plants in flower at the time of our visit: *Tecoma stans* and *T. capensis*, the former with yellow, the latter with scarlet flowers—both splendid bushes. *Carica Cundinamarcensis* was both in flower and fruit. *Statice rosea*, a south African plant with charming, rose colored blossoms, was represented by a big, dense bush clothed with flowers; under cultivation in England it is rarely satisfactory. *Russelia juncea* and *Plumbago Capensis* gave an abundance of blossom, and in one or two spots the splendid blue trumpets of *Ipomœa Learii* formed quite a dazzling sheet of color; never under glass in England had my companion or myself seen this climber to such advantage. *Correa cardinalis*, the most beautiful member of this Australian genus, was noted as especially attractive; not far from it another Australian plant, *Pimelea decussata*, was also in flower. *Lochroma Fendlerianum*, with purple blossoms; *I. coccineum*, with scarlet ones, and the Humming-bird's Trumpet, *Zauschneria Californica*, made an attractive trio. The huge, white flowers of *Cereus Napoleonis* were especially striking, and on a "pergola," or walk with a sort of flat, trellised roof clothed with a bewildering array of climbers *Passiflora Decaisneana*, with its large, handsome flowers—in form and color not unlike those of *P. alata* and *P. quadrangularis*—was very conspicuous. On the low stone wall on one side of this walk numerous species of Begonia, *Æschynanthus*, many Bromelias—some of these in flower—*Cypripedium insigne*, etc., flourished in the shade.

Mr. Hanbury has paid special attention to economic, particularly medicinal, plants. As most of these, however, are not of value from an ornamental standpoint, I pass them over. A large collection of Orange-trees, etc., gathered together from all parts of the world where Oranges are cultivated, affords means for studying and comparing the various forms of this puzzling family which do not occur in every country. A large bush or small tree of the curious Chilian *Quillaja Saponaria* was laden with its woody carpels, which, at first sight, by no means recall the order Rosaceæ, to which the plant belongs. The thick bark is rich in saponin, which can be procured from it purer and more plentifully than from any other source; up to the present the principal use has been in washing and cleansing fine stuffs and tissues; but recently, however, the discovery of the action of saponin or a decoction or infusion of Quillaja bark on hydrocarbon oils, has opened out great possibilities for its use. Such extremely inflammable oils as benzoline—the dangerous character of which rendered the utmost care necessary in packing, carrying, etc.—can now be solidified and shipped with little danger or trouble—the liquid condition being readily restored on arrival by the addition of a small quantity of citric acid.

A covered way clothed with *Ephedra altissima*, a member of the order Gnetaceæ, a family nearly allied to the conifers, was gay with the numberless coral-red fruits which weighed down the green, leafless, twiggy branches. Probably the Kaffir Plum or Kei Apple, of south Africa, fruited for the first time

in Europe in Mr. Hanbury's garden some years ago. At the time of our visit the tree was laden with its yellow plum-like fruits, somewhat acid in taste and astringent in character. One of the most beautiful of all the fruiting herbaceous plants was a Solanum received from Vilmorin, Andrieux & Co., under the name of *S. ciliatum macrocarpum*. It had a spiny stem and leaves, and spreading branches borne down by the weight of the large, bright vermilion-red fruits; on comparing with herbarium specimens it appears to be identical with the Brazilian *S. aculeatissimum*.

A south African plant, a composite from the Karroo region, though not in flower at the time of our visit, is interesting on account of its having, more than any other at La Mortola, won the admiration of Queen Victoria when she visited Mr. Hanbury's garden in March, 1882. The plant in question, *Pteronia incana*, forms a dense, twiggy shrub, and has small, ashy gray leaves. The pretty yellow flower-heads so charmed the Queen that she took away with her a quantity of the flower-laden branches. Since then the species has been called in the neighborhood, "La pianta della reina"—the Queen's plant.

At Mentone, which is so near La Mortola that the climate of the two places must be almost alike, the mean temperature of November is fifty-four degrees Fahr., December forty degrees, February forty-nine degrees, and March fifty-three degrees. Nearly the whole of the annual rainfall takes place during the winter and spring months; during summer only an occasional thunder-storm comes to moisten the thirsty ground. The storing of water, therefore, for use during the hot, dry summer months is an absolute necessity, and entails much labor and expense.

New or Little Known Plants.

Viburnum pauciflorum.

THIS pretty species, which attains a height of three or four feet only, might be described as a dwarf *V. Opulus*, with small cymes, terminating short, two-leaved, lateral branches, and without the showy neutral ray flowers of that species. It is a widely distributed northern plant, inhabiting cold, moist woods from Labrador to Alaska, extending south to the high mountains of northern New England, the Saskatchewan country, Washington, and to the Rocky Mountains of Colorado. *Viburnum pauciflorum* has recently been introduced into the Arnold Arboretum, where it has not, however, flowered. The small figure of a flowering branch from Alaska is Regel and Herder's "Plantæ Raddianæ" (iii. t. 1, p. 3), is the only one published previously to our illustration upon page 5, drawn by Mr. Faxon from specimens gathered among the White Mountains of New Hampshire.

Foreign Correspondence.

London Letter.

THE year 1889 is practically over, so far as public horticulture is concerned. Exhibitions are at an end, the final periodical meeting has been held, and the only remaining attraction is a public dinner or so, at which hand-shaking and general back-patting will be in order. English horticulturists appear to be cultivating a love for public dinners in connection with their clubs, societies and shows; at any rate, they are much more frequent in recent years than they were formerly.

Next week I hope to be able to notice the principal additions that have been made this year to the list of good garden plants in England. Speaking from memory, I do not think there is anything remarkable to record in the way of new introductions. On the other hand, some very fine hybrids, crosses and varieties of garden origin have been added. Collectors confine their work chiefly to Orchids, so that comparatively little is to be expected from them. Hybridization is the great attraction of the time, and almost every man who has a garden tries his hand at crossing one plant with another, in the hope of getting something startling.

The last of this year's bi-monthly meetings of the Royal Horticultural Society was held on Tuesday, December 10th. Circumstances are totally against anything approaching a successful exhibition, or even a good muster of fellows in the middle of December. Despite this there were several exhibits

of more than average interest, and others which were worth going to see. Orchids were represented, first, by a basket of choice plants from Messrs. F. Sander & Co., amongst which were *Odontoglossum Wattianum*, the new species noted in my last letter: It is not bright in color, nor uncommon in form, and may be called a mixture of *O. luteopurpureum* and *O. Sanderianum*. Another plant shown as new, and named *Cattleya O'Brieniana*, is a variety of *C. Loddigesii* with the petals slightly broader and less curved. *Dendrobium Slatterianum* is a good variety of *D. bigibbum*, very dark in color,

spikes with 346 expanded flowers upon them. It would be difficult to surpass this *Masdevallia* as a free flowering, easily grown plant, but the specimen shown was a surprise even to those who know the good qualities of the species. Mr. Hodgson had grown this specimen from a tiny plant with two leaves, which he purchased for a guinea fifteen years ago.

Cælia bella is a Mexican Orchid which is not common in cultivation, but a plant of it shown by Mr. Malcolm Cook was ornamental enough to attract attention. It bore eight spikes of flowers, each spike with from four to six expanded

Fig. 1.—*Viburnum pauciflorum*.—See page 4.

the lower part of the lip being of a deep maroon; the middle lobe of this organ is also longer than in *D. bigibbum*. Some persons who saw it were inclined to call it a variety of *D. Phalenopsis*, and thought it might be a connecting link between that species and *D. bigibbum*. Whatever its affinity, *D. Slatterianum* is a pretty addition to the Australian *Dendrobiums*. *Aërides Savageanum* is a small flowered addition to the numerous, and, as a rule, handsome-flowered group of species represented by *A. odoratum*.

Masdevallia Tovarensis was exhibited in superb condition, the plant bearing 255 leaves, all perfectly healthy, and 162

blooms, which were two inches long, tubular, the segments spreading, recurved near the apex, and colored white with crimson lips; the lip is triangular and sulphur yellow in color. *Cælia* is a genus of some four or five species, three of which are in cultivation at Kew, but only *C. bella* is handsome enough to rank with garden Orchids. It has been in cultivation many years, and used to be known as *Bisfrenaria bella*. There is a figure of it in the *Botanical Magazine*, t. 6628.

Cypripedium Niobe, a hybrid whose parents are *C. Fairreanum* and *C. Spicerianum*, is one of the most charming of the

smaller hybrid kinds of *Cypripedium*, combining, as it does, the characters of two of the best species in the genus. The dorsal sepal is broad and recurved as in *C. Spicerianum*, but greener at the base and veined with purple. The petals are wavy, curved as in *C. Fairreanum*, deep green and bronze, the lip being small and greenish. Three plants of it in flower were shown by Messrs. Veitch, who raised it, and to whom a first-class certificate was awarded for it.

Other hybrids shown were *T. B. Haywood* (from *C. Druryi* and *C. superbiens*), *C. Galatea major* (from *C. Chantini* and *C. Harrisianum*), *C. Lceanum* and *C. Lathamianum*.

Cattleya Pallas, a hybrid raised from *C. Dowiana* and *Lalia crispa*, was also certificated, but its only good point was the color of the lip. In attractiveness the flowers were inferior to those of a good form of either parent. *C. Dowiana* has had little influence either on the color or form of the flowers. *Panda Amesiana*, with a strong spike of flowers, was shown by Lord Rothschild. Apparently there is some variety of color amongst the plants of this Orchid; some of them being inferior to others in the depth and clearness of the purple on the labellum.

Mr. Cannell showed a stand of cut flowers of *Zonale Pelargoniums*, for the cultivation of which he is famous. In England, and especially in the neighborhood of London, it requires considerable care and skill to bloom these plants well in December. When grown as Mr. Cannell grows them, with enormous trusses of flowers full of substance and clear in color, they are of the greatest value in winter. The best of those shown were the following: White flowered kinds, *Swanley White* and *Amy Ampheet*; pink, *Mrs. D. Saunders* and *Mr. Wildsmith*; pale blush, *Stella* and *Massey*; salmon, *Souvenir de Mirande*; scarlet, *Hyacinth* and *Brilliant*; purple or magenta, *Dr. Tucker* and *R. Dean*. I mention these because I do not think it possible to find better kinds amongst the many large-flowered *Pelargoniums* now grown. There are a few ardent admirers of these plants, conspicuous amongst them being Mr. Chamberlain, who devotes a large house to them in winter, and delights in their flowers as much as he does in Orchids. Mr. Cannell also showed flowers of *Chrysanthemum Mrs. E. W. Clark*, a child of America, I believe, and remarkable for its fragrance. It is a large flowered incurved Japanese kind, colored deep purplish magenta, and not very attractive. *Crimson and Gold* was another of Mr. Cannell's *Chrysanthemums*. It is one of the so-called single flowered section, and has a large, dark yellow disc with crimson ray florets flaked with yellow.

Some well flowered panfuls of the pretty, snow white *Narcissus monophyllus* came from Mr. Ware, of Tottenham. A few years ago this plant was extremely rare in cultivation, and was very difficult to manage. Now, however, it is easy to grow and flowers if only the bulbs are kept quite dry and baked in full sunshine all summer. It is a native of Algeria, where it occurs in abundance. Newly imported bulbs always flower with us in December, but after a year's cultivation in England they do not come into bloom before February. It may not be known to every one that *N. monophyllus*, sometimes called *Bulbocodium monophyllum*, has short, rush-like leaves, and pure white, hoop-petticoat-like flowers, in form like those of the well known *N. Bulbocodium*. The flowers remain fresh a month or more. One of the most striking of the exhibits was the *Carnation Winter Cheer*, the plants being less than two feet in height in perfect health, and covered with large full flowers, two and a half inches across, of the brightest crimson color. It would be difficult to find a better winter-flowering *Carnation* than this, and I am told it is one of the very easiest to grow.

The most attractive among the flowering plants in our stoves at the present time are *Ipomœa Horsfallii*, with its variety, *Briggsii*, and the closely allied species, *I. ternatea*. The first named extends over half the roof of the stove, its many shoots hanging down or festooned from pillar to pillar, and crowded with large clusters of rich, deep crimson, cup-like flowers. It has been beautiful for a month or more and will continue so at least as long again. The variety *Briggsii* has paler and slightly smaller foliage and rosy red flowers, whilst *I. ternatea* has flowers as large as those of the *Morning Glory* and as pure a white. We miss this year another beautiful flowered species of *Ipomœa*, that is, *I. rubro-cœrulea*, a stove annual, which may be grown so as to bloom in midwinter. Treated liberally, it covers a large space in a short time, and in winter its shoots are wreathed in large, flat-limbed flowers of the purest china blue, fading to mauve. That remarkable species, the *Moon Flower* of the tropics (*I. Bona-nox*), whose great white flowers expand only at dusk and close at sunrise, has also been flowering here for some time. I measured a flower lately, and it was exactly six inches across.

Kalanchoe carnea.—I am afraid that this new introduction has been somewhat overrated; at all events, none of the examples I have seen this year are sufficiently attractive to rank among good conservatory winter flowering plants. The habit is erect, branching, about two feet high, the leaves coarse and soft, and the terminal heads of flower, whilst large and full enough, are too undecided in color, being neither white nor rosy, but a dull milky color. With good cultivation and selection there may be something of value got out of this plant, but the type does not please. It was introduced last year from south Africa, and received a first-class certificate from the Royal Horticultural Society. *Begonia geranioides* is one of the most charming of late or winter flowering species. It is deciduous, about a foot high, and produces numerous erect peduncles of elegant pure white flowers. A group composed of three dozen or so plants of this species, *B. Socotrana* and the variety *John Heal*, mixed together, is one of the most charming pictures one could desire to see in November or December. *B. geranioides* is a native of the Cape.

Cultural Department.

Sowing Seed.

THERE are few good sowers of seeds. To buy seeds and to cover them with earth comprise the sum of practice with many people, and failure to get the most from seeds means more than the loss of the seeds themselves, for it is indication of general incompetence or shiftlessness. To sow well is the first operation to acquire in gardening; propagation by cuttings is the second.

Two or three general rules are fully as important as many of the explicit instructions: 1. Do not be in a hurry. In all my teaching how to sow it is necessary to make this the important point. It means taking an abundance of time to prepare soil and to provide proper conditions. Ten seeds well sown are more valuable than fifty half sown, and, as a rule, the more valuable the plants to be grown the more imperative is this rule. 2. Avoid short-cuts which are wholly artificial. In all the long catalogue of compounds devised to hasten germination, I do not know one which is worth its cost or trouble. It is always legitimate to hasten germination, but it must be done by perfecting natural or normal conditions. 3. In cases of doubt as to the proper method of handling rare or choice seeds, sow in installments, at intervals. This means experiment. With practice comes an almost intuitive faculty to determine at once what are the proper methods of dealing with seeds with which we have never had experience. But until this faculty comes, safety demands caution. And some people never acquire the faculty. The gardeners of my acquaintance are comparatively few to whom I would entrust an entire sample of strange seeds from another region; not because I could do better with them, but I can learn from a few how to handle many. I once failed completely in an attempt to grow weak seeds of a couple of species, although the year after, profiting by failure, I secured an abundance of fine plants from the same samples.

Seed-sowing comprises three distinct subjects: 1. Selection of the seed. 2. Treatment of the seed preparatory to sowing. 3. The sowing itself. In the first division are to be considered all those questions concerning the age of the seed, the condition of the parent plant, weight, color, and so on. These matters are too extensive for discussion here. The remaining points may be considered.

TREATMENT PREPARATORY TO SOWING.—There are many kinds of seeds which demand some particular treatment before sowing. These are seeds of most fruit plants, nuts and bony seeds, and various sorts of pulpy fruits. The pulp of fleshy seeds and fruits should be removed before seeds are sown. The pulp is usually removed by maceration. The berries of Red Cedar, Raspberries, Cranberries and the like are mashed or bruised and placed in water until the coverings become soft. This occurs in a few days in such soft fruits as Raspberries and Blackberries. The pulp rises and the seeds settle, and it often becomes an easy matter to separate them; or, if the pulp still adheres to the seeds after a short period of maceration, it may be cut by the addition of a half stick of caustic potash to a pail of water. The seeds are allowed to remain in the potash water but a few hours at most, when they are strained out and rinsed in fresh water. They are then spread upon tables to dry. Sometimes I remove the pulp by rubbing the seeds in sharp sand. The fruits are buried in clean, sharp sand until the fleshy portions become nearly dry, when the whole mass is rubbed through the hands until the

Fig. 2.—A Cypress Swamp in Southern Indiana.—See page 2.

seeds are liberated. It is often impossible to separate the seeds from the fragments of pulp and the particles of sand, nor is it necessary to do so. I sow sand, pulp, seeds and all, in many cases. In the case of rare seeds, however, I manage, by sifting the sand before it is used, to sift out the seeds with tolerable accuracy. In all cases in which the seeds are few and valuable, I should prefer to rub them out rather than to macerate them. There are some seeds which are injured by maceration, unless the operation is expeditious.

All seeds with bony coverings, such as nuts, pits and the like, should be procured as soon after maturity as possible, and put in stratification during the winter. This operation consists in burying seeds in layers of clear sand and exposing them to the weather of winter. A layer of sand an inch or two deep is placed in the bottom of a pot or box, and alternate layers of seeds and sand are added until the pot is full. The pot is now buried a foot or so below the surface in a sandy and well drained soil, or it is placed in a partially protected pit. This prevents the seeds from becoming hard and dry, and the freezing and thawing, with a little variation in moisture, soften or rupture the integuments. It is a popular notion that freezing is necessary to the germination of Peach-pits and similar seeds, but this is an error. Freezing hastens germination by hastening the rupture of integuments, but artificial

cracking is as good. It usually happens, however, that buried pits, even though not split by frost, germinate better than those stored in a building and cracked by hand, but this is due to the fact that the buried seeds have not been allowed to become dry and hard. There are certain seeds and fruits which demand particular methods of handling for purposes of convenience. I stratify walnuts and butternuts by heaping them into a pile out-of-doors, mixing in sand and leaves. Acorns are simply kept in boxes of moist leaves. If the seeds are small and few, I place them between layers of thin muslin before stratifying them. They are then easily separated from the sand.

Stratification and sowing may sometimes be combined. If the ground is well drained and well prepared, seeds of Apples, Pears and berries may be sown in the fall, where they are to grow, with good success. I rarely have good success with Apple and similar seeds purchased of seedsmen. The seeds have been so thoroughly dried that they are often past recovery. The best practice in such cases, probably, is to soak the seeds a few days, exposing them to a few sharp frosts. If fruit seeds are to be transported they should be packed in some material which will preserve tolerable uniformity of moisture. Pear-seeds which I have imported from France, packed in powdered charcoal, have germinated speedily.

Many hard seeds do not germinate the first year, even with the best treatment. The seeds of Thorns and other wild fruits belong to this category, and even the seeds of many herbaceous plants behave similarly. Sedges often require two years in which to germinate, and it is unusual for seeds of the wild perennials to germinate until the following spring, even if they are sown as soon as they are ripe. All that can be done with such seeds is to sow them in permanent beds and keep the land clean until the plants appear. I prefer to sow rare seeds in pots. The pots are then plunged in earth in a cold frame, which is placed on the north side of a building or in such a position as to be partially screened from the sun. The frame is then covered with a sash, or, better, with plant-bed cloth. About 100 pots of seeds of Sedges and other wild herbs were sown here last spring, and at the present time less than one-fourth of the kinds have germinated. The pots in which plants have appeared will be plunged in a pit in order that the roots

may not freeze dry, and the remainder will remain for a year or two until germination takes place.

MANNER OF SOWING.—Only general hints can be given as to the manner of sowing. Explicit instructions must come with instruction for the cultivation of the particular species. Much has been said concerning the depth of sowing, and rules drawn from the size of the seed have been made; but arbitrary instruction cannot be given. In houses where uniformity of moisture can be maintained, people sow too deep oftener than too shallow. Simply covering the seeds with soil enough to hold moisture is sufficient in most cases, and seeds thus planted are not liable to rot or to be delayed by too much water. The condition of the soil as concerns moisture must always determine the depth of planting in the field also. Plant deep in dry soils and shallow in moist soils. In other words, plant just deep enough to ensure uniformity of moisture.

In fact, the commonest cause of failure in seed-sowing is too much moisture. This is particularly true in the case of old and weak seeds, which are quickly killed by much wetting. Seeds from remote parts of the world, or which, I have reason to suppose, possess low vitality, are never watered directly. They are sown in a pot, and this pot is set inside a larger one, and the intermediate space is filled with sphagnum or packing moss. The water is applied to the moss, and it passes through

the inner pot and into the soil. The seeds of two species of *Capsicum*, injured by too great heat in drying, failed completely in 1888 when sown in pots and watered in the ordinary manner; but this year seeds from the same saving were sown in the way described, and all, or nearly all, sprouted quickly. Thomas Andrew Knight used to sow rare seeds by simply placing them between dry sods from an old pasture. But any method which ensures uniformity of moisture, and a small amount of it, will give success. Recent tests conducted in our houses show conclusively that seeds usually receive too much water.* There is even danger, as we have sometimes found, of keeping the soil too wet through the use of the sphagnum process outlined above.

So I repeat that the most important point in sowing is the relation of the seed to moisture. I prefer to sow shallow, and then to pack the earth to retain moisture, or if the earth is liable to bake, I cover it lightly with leaves or fine litter, or with boards. Very small seeds I sow upon the surface of well prepared soil, and then sprinkle a very little fine soil over and among them; then I cover with paper, or with a board or something to prevent excessive evaporation. I rarely expose the pots or boxes of such seeds to the light, for the heat of the sunlight accelerates evaporation. It is largely the uniformity in moisture which causes the results of seed tests to read higher than the results of actual sowings in the field. Eight experiments to determine the percentage of variation between tests made in the house and sowings made in the field, with seeds from the same packets, gave the following differences: Pea, 1.1 per cent.; Endive, 17.5; Tomato, 25.5; Celery, 30; Onion, 32; Carrots, 42.5 and 50.5; Turnip, 57.5. These remarkable variations were almost wholly due probably to variations in moisture in the field sowings, and yet the soil in which the sowings were made happened to be unusually and uniformly moist for a light soil.

Cornell University.

L. H. Bailey.

Stove Plants in Flower.

AMOMUM MAGNIFICUM.—*Amomum* is a large genus of tropical Gingerworts, and is related to *Hedychium*, *Curcuma*, etc. Of the fifty species described, that under notice is by far the handsomest; indeed it is the only one which can be considered of any horticultural merit. Although introduced into England in 1832 by Lord Milton and flowered in his garden at Wentworth, it does not appear to have kept a place among garden plants. The picture in the *Botanical Magazine*, t. 3192, gives a good idea of the remarkable character and beauty of this species, and I believe it was on seeing this picture that Sir George Macleay, of Pendell Court, one of our most enthusiastic amateur gardeners, procured plants of it from Mauritius, where it has become naturalized, having been introduced from Madagascar, its home. The plant at Pendell Court has just flowered, and the inflorescence has been forwarded to Kew. In habit and general appearance *A. magnificum* is similar to *Alpinia nutans*, but the stems attain a length of twelve feet, whilst the lanceolate leaves are two feet long, or even more. In *Alpinia* the flowers are in terminal heads on the leafy stems, but in *Amomum* they are borne on a separate stem or scape, which is leafless and about four feet high. The flowers are arranged in a dense conical head, which is surrounded by eight or ten large bracts, four inches long by two inches wide, rather fleshy, recurved and colored rich cardinal, the margins being white; in addition to these large bracts, each of the hundred or so flowers is overtopped by a smaller spatulate, curled bract, similar in color to the large ones. The effect of this head is really fine. The plant grows in wet places, that at Pendell Court being in the corner of a tropical tank on a large mound of mud-like soil. It is similarly treated at Kew. For cultivation in large tropical stoves, and especially for aquaria, this plant may be specially recommended. It has been called *Alpinia magnifica* and *Nicolaia imperialis*.

RHIPHALIS HOULLETTII.—Several good specimens of this ornamental plant are now flowering freely at Kew. The genus *Rhipsalis* is scarcely known in gardens, owing to the smallness and lack of ornament in their flowers generally. Botanically, however, it is one of the most interesting of the genera included in *Cactaceæ*, the great variety in the form and habit of the stems of the thirty or so species known being quite exceptional. Some resemble Mistletoe, others Marsh Samphire, others *Mesembryanthemum*, others *Epiphyllum* and so on. A collection representative of the most marked species is grown at Kew, and it always attracts attention. The genus is also interesting from the fact of its being the only one among the *Cactaceæ* found wild in Africa, Mauritius, Madagascar and Cey-

lon, as well as in America. *R. Houlettii* has long, graceful branches, partly round and twig-like, partly flattened, as in *Phyllocactus*. It branches freely, and when well treated it forms a well furnished, elegant pot-plant. The flowers are borne singly in the numerous notches of the flattened portions of the branches. They are nearly an inch across, not unlike those of a *Mamillaria* in form, and colored pale creamy yellow, with a crimson eye-like spot in the throat. They are also fragrant. Under cultivation the plants are about three feet high, but in its native haunts it hangs from the trunks of trees to a length of many feet. All the *Rhipsalis* are epiphytic in a state of nature, but they thrive when cultivated in pots or baskets in a light stove. Flowering in November and December, *R. Houlettii* is worth growing in every collection of stove plants. It is native of Brazil.

Kew.

W.

Orchid Notes.

***Dendrobium formosum*.**—This is without doubt the finest white-flowered *Dendrobium* yet known, its blooms far surpassing those of its allies, *D. Draconis* (perhaps better known in gardens as *D. eburneum*), *D. infundibulum* and *D. Jamesianum*. It has a wide geographical distribution, being found in north-eastern India, Burmah, extending to Moulmein, and it grows also along the coasts of the Andaman Islands, and is consequently subject to variable climatic conditions. It has been over half a century in cultivation, the first plants of it having been sent to Chatsworth in 1837 by Gibson, who found them on the Khasia Hills. Its first discoverer, however, was Roxburgh, who detected it growing in Sylhet five or six years earlier. The characteristics of *D. formosum* are its stoutish terete stems, which when young are covered with short blackish hairs and furnished with ovate-oblong, deep shining green leaves, four or five inches long, and obliquely emarginate at the apex. The old stems are deeply furrowed, leafless, and often clothed with dull silvery sheaths. From September to Christmas fascicles (or clusters) of from three to five large flowers are produced at the top of the young stems before these latter have finished their growth; but it is not unusual, however, to see the old stems also bearing flowers. The sepals and petals are pure white, the former being oblong-elliptic and keeled behind, the two lower ones connate at the base and produced into a spur. The latter are much broader and obovate, while the white lip, which, when spread out, is rhomboidal retuse, but more or less funnel-shaped in its natural position, has a stain of bright orange-yellow on the disc, the latter being traversed by five slightly raised and asperated keels.

The variety known in gardens as *D. giganteum* is remarkable for the extraordinary size of the flowers, which are half as large again as those of the ordinary type, often measuring from four to five inches across.

Plants of this species may be grown either in pots or baskets, but the latter are preferable, as, when wires are attached, the plants can be hung nearer the glass, and thus obtain a clearer light. Plenty of heat and moisture are essential to them during the season of growth, and they may be freely watered and syringed. The flowers appear on the growing stems, and when they have disappeared it is generally a sign that growth has almost ceased, and the plants should then be placed in a slightly cooler house to rest for two or three months, only receiving water at intervals in order to keep the growths from shriveling. A compost of rough fibrous peat, with a little sphagnum, is very suitable for them.

St. Albans, England.

John Weathers.

***Lælia Crawshayana*.**—This very rare and interesting Orchid is now in flower with us. It is presumed to be a natural hybrid between *L. anceps* and *L. albida*.

The inflorescence strongly resembles the former, while the vegetative organs are almost identical with those of *L. albida*. It certainly is a great improvement on the latter, while retaining all its pleasing Primrose-like fragrance. As is the case with most hybrid Orchids, this is a robust grower. The clustered bulbs are compressed, pyriform and slightly furrowed, bearing one or two lanceolate acute, leathery, deep green leaves. The scape proceeding from the top of the bulbs is about eighteen inches long, jointed, with sheathing keeled bracts, terminating in a cluster of three to four flowers. These are about three inches across, with narrow sepals and broader petals of dark rose. The narrow three-lobed lip is white, with the side lobes tipped with rose, and the anterior one rosy purple. Lines of yellow run down the middle of the lip, and the throat is streaked with maroon. *L. Crawshayana* was introduced six years ago, and but very few plants are yet in cultivation.

* Bulletin ix., Cornell Experiment Station.

Lælia Gouldiana, like the preceding, is a natural hybrid, having for parents *L. anceps* and *L. autumnalis*, but it does not betray its origin in so marked a degree. Its vegetative organs vary very little from those of *L. autumnalis*, except that the bulbs are more slender and furrowed. The leaves are long and narrow—either one or two on a bulb. The flowers partake of the characters of both parents, but the petals are broader than those of either, more resembling Dawson's variety of *L. anceps*. The lip is shaped like that of *L. anceps*, with the lobes purple-crimson and a bright yellow crest. The sepals and petals are of a very dark rose, intensified at the tips. The scape is about eighteen inches long and bears four to six flowers. It is a very handsome Orchid, but, unfortunately, it has inherited the repugnant odor of *L. autumnalis*. *L. Gouldiana* is an American introduction, having been found among a batch of Mexican Orchids imported by Messrs. Siebrecht & Wadley three years ago. It is now fairly plentiful. Another species of this series has recently flowered in a New York collection, and it is evidently a hybrid between *L. autumnalis* and *L. albida*. I am told the growth is very like the former, but I have only seen one flower, which I thought very pretty, and which seemed intermediate between its supposed parents. This plant is not as yet named.

Miltonia (Odontoglossum) Razlii is nearly always in flower with us, and we find it very useful for cutting, as it lasts quite a long time in water. We always found it difficult to grow so long as we treated it as a cool Orchid. It would gradually dwindle away and be eaten up with thrips, and we seldom saw a flower. We now grow it in the hottest corner of the Phalænopsis house, with the glass extra shaded even in winter. We keep the plants very wet and syringe them two or three times a day. Under this treatment they grow like weeds, making leaves sixteen inches long by one inch broad, and fine, stout bulbs, which improve every year, and produce two or three racemes apiece. Thrips are never seen now. The soil we use consists of equal parts of sandy peat and moss, using small well drained pots. *Miltonia Razlii* was discovered in the warmer regions of Columbia in 1873. The bulbs are somewhat compressed, ovate-lanceolate, two or three inches long, surmounted by one or two linear-lanceolate leaves, and from the base of the bulb spring pairs of long leaf-like bracts which enclose the three to four flowered racemes. The whole plant is of a uniform pale green color. The flowers are large, and pure white, excepting a blotch of rich crimson-purple at base of the petals. The lip is large and flat, comprising two-thirds of the flower, pure white, stained with yellow at the base, from which radiate narrow lines of brown. The variety Alba is inferior to the type, from which it differs in having no blotch at the base of the petals. The value of the flowers is enhanced by a very pleasing fragrance.

F. Goldring.

Kenwood, N. Y.

Christmas Roses.—It is to be hoped that the two interesting articles on Hellebores, in GARDEN AND FOREST of December 18th, will lead to discussion and additional notes from cultivators. The best varieties of Christmas Roses are perhaps the largest and most attractive flowers which bloom at so low a temperature, and they are very desirable in gardens if established in suitable locations. They are Alpine plants, and naturally bloom as soon as melting snow exposes their buds to the sun's influence. Planted on a rockery with a northern exposure no doubt they would follow out their natural course; but we wish them to bloom during the winter with as little protection as possible, for they need protection in an ordinary season in this latitude. Mr. Orpet's record of successful bloom in the open ground probably could not be often repeated; this season having been remarkable for its freedom from binding frosts, by which these plants are promptly made dormant. Hellebores have excited much interest in recent years, and rather divergent cultural directions have been given, as in the notes spoken of one advises light soil, the other retentive. Both recommend shade, while Mr. H. Correven ("Les Plantes des Alpes") says they require a deep, heavy soil and exposure to the sun. As usual, when such varying directions are given, it will be found that plants will grow any way if given a fair chance. Hellebores appear less amenable to good treatment than any plants which have come under my observation, and pursue the cycle of their growth with little deviation, so far as I can see, from any extra care. As to division, my best flowers this season were from plants divided in June. The problem is not so much how to grow them, but how to bloom them as is done in England and Ireland during the winter, so that one can enjoy them. The climate in my locality will not usually admit of their open-air culture after December 1st, and I keep them in a warm cold frame; but my floral enthusiasm does not go so far as to

enjoy flowers blooming in a frame. A cold house from which frost is excluded would probably meet their requirements exactly. This year noticing that some bits of Madame Fourcade, which happened to be in the greenhouse, grew away vigorously when heat was started, I have tried the experiment of blooming a few plants there in the coolest part. *H. abchasicus albus* and *H. purpurascens* (which are usually known as Lenten Roses) bloomed very well. *H. Caucasicus* gave me beautiful flowers, while the buds of *H. ruber* and *H. angustifolius* are still unmoved. New leaves are starting, and I am interested in the result of the experiment next season. One authority says I shall lose my plants, another that I shall lose my flowers. As plants growing vigorously do not seem in great danger of death, perhaps the next blooms may appear when due. A number of consignments of Hellebores are received and sold in New York annually. They are usually Lenten Roses, often Dutch Hybrids. The major part probably perish promptly from wet and rot when planted out, victims of the tradition that Hellebores bloom in the snow at Christmas.

The Forest.

Forests and Floods.

IN connection with the propositions of the Forestry Congress at Philadelphia and the American Association for the Advancement of Science in Toronto recommending the establishment of a Commission to inquire into the relation of the forest areas on our western mountains to the water supply of those regions, it will be of interest to note two publications just issued from official sources in Europe. The one is the draft of a bill for a new forestry law in Austria, accompanied by a detailed report setting forth the reasons for the provisions of the law; the other is the report of a royal commission of Baden, appointed to investigate the connection of the forest conditions of a section in the Black Forest with the disastrous floods of the Rhine in the winter of 1882.

The first report, from the able pen of the Imperial Privy Councilor and well known meteorologist, Dr. Lorenz von Liburnau, discusses briefly and in general our present knowledge in regard to forest influences on climate and water flow, reaching the conclusion that, while many of the popular ideas on these subjects are derived from imperfect observation and are, therefore, without foundation, or, at least, unproved, nevertheless the evidences from scientific investigation that these influences do exist are sufficient to warrant a conservative forest policy on the part of the government.

The report of the Royal Commission of Baden concerns itself with a special case and is of unusual interest, as it presents for the first time a thorough, though only partial, investigation into the relation of forests and floods. That the verdict in this case is negative does not detract from the value of the report, as showing the method by which this question must be treated; nor does it follow—and the commission takes pains to make this statement—that a generalization or final settlement of the question has been reached by this investigation.

This commission was composed of an officer of the Central Bureau for Meteorology and Hydrography, an officer of the Engineer Department, and an officer of the Forestry Department. The work of this commission was called forth by the disastrous floods of the Rhine and its affluents in 1882-3. These led, also, to the appointment by Prince Bismarck, as Chancellor of the Empire, of a commission for the purpose of studying the Rhine, to determine whether there had been such a deterioration in its water conditions as might justify reforestation and the construction of reservoirs, or the adoption of some other plan than correcting the river-bed in the upper portions of the affluents. The Baden Commission made a very careful survey in that part of the Black Forest which forms the watershed of the Alb River, one of the smaller affluents of the Rhine.

Such a survey comprises not only the geographical, climatic and geognostic conditions of the water-shed, but more specially gives detailed descriptions of the various kinds and uses of the soil, whether under tillage or in pasture, meadow or forest, swamp land or moor land. It explains the systems of water-courses, the utilization of the waters by mills, etc., and the damage done by floods and other unfavorable conditions of waterflow. A few of the data, which together give a comprehensive view of the region, may be of interest for the understanding of the conclusions reached. The watershed discussed comprises 93.5 square miles, the larger part (fifty per cent.) with slopes varying from ten to thirty degrees. The

precipitation at two stations situated at altitudes of 3,310 feet and 1,250 feet had been in an average of fourteen years sixty-five and fifty-eight inches respectively, while during the year 1882 it reached eighty-nine and eighty-one inches, or about thirty-eight per cent. more than usual.

Of the soil, which, for the most part, is derived from granites, gneisses, sandstones and clay-slates, eighty-six per cent. were found impermeable. Forest occupies fifty-one per cent. of the whole area, very unevenly distributed, showing, in the various localities, a range of from twenty-two to ninety-one per cent. Of this, sixty-three per cent. is composed of Spruce, the balance of Beech. The forest, to the amount of sixty-one per cent., was owned by private individuals, in small parcels; and this part was found more or less in poor condition, owing to mismanagement, with openings or thinly stocked places, especially along steep slopes, with poor roads and suffering from destructive pasturage. The forty-nine per cent. of government and communal forest was in good condition.

Some of the conclusions and observations, in which the report abounds, are as follows: First. The observations at the two stations mentioned before "justify the conclusion that the large percentage of forest (fifty-one per cent.) has caused a considerable increase of rainfall." For, while the average amounts of precipitation for Germany at the same, or nearly the same altitudes, are twenty-seven and a half and thirty-eight inches respectively, the values at these stations, as stated above, are thirty-four per cent. and fifty-seven per cent. higher.

Second. The retention and retardation of waters, and especially the slower melting of the snow under the forest cover, is acknowledged. In exceptional cases, however, this influence of the forest, it is stated, may become ineffectual, namely, during an unfavorable sequence of periods of heavy precipitations, as was the case in the catastrophes of 1882.

Third. "Entirely beyond dispute, and, hydrologically, of the greatest importance, is the binding of the soil effected by a forest cover, and, in this respect, the forest of the Alb watershed fulfills its function as a protective cover fully. The satisfactory condition of the water-courses and valley-bottoms and the moderate extent of the damage experienced from the floods in this watershed are due to the small amount of detritus. The soil conditions being extremely favorable to the formation of detritus and rock chutes, their absence can only be due to the forest cover on the declivities." Where such masses of detritus and waste rock and landslide material are found (on about sixty acres) they can be traced to improper deforestation and pasturage.

Fourth. An influence of the forest on the flow of springs could not be stated in the region, although it cannot be generally denied.

Fifth. The employment of flood-reservoirs is discounted, as disproportionately expensive.

Sixth. The influence of the Alb forests on the waterflow is stated in summary to the effect that, while the forest could not have prevented such an extreme flood as that of 1882, yet, on the other hand, to the forest is due that the Alb watershed experiences such disasters "only very rarely," and more rarely than adjoining valleys with a smaller proportion of forest area.

This report, treating the question of forests and floods without any preconceived theory to prove, will impress the reader with the fact, which cannot be too strongly insisted upon, that only a careful survey of local conditions can enable us to determine how far in any given case a forest cover acts upon hydrologic conditions.

Not only do rainfall conditions, and the conditions of the forest itself, determine the office of the latter in water distribution, but the geological and physical conditions of the soil and its topography, the conditions and comparative length of the water-courses, are also prominent factors of influence. These are elements which enter into the discussion of the character of the "run-off" only; when the broader question of available water supplies is considered many new elements enter, such as the interception of rainfall by the foliage, the dissipation of water by evaporation, by transpiration, by seepage, and in other ways.

Department of Agriculture, Washington, D. C.

Correspondence.

The India Rubber-Tree.

To the Editor of GARDEN AND FOREST:

Sir.—Referring to the article upon the India Rubber-tree published in your issue of November 13th, it is, perhaps, worth while to call attention to the ease with which that beauti-

ful tree can be propagated for cuttings. As is well known, it is only necessary to take a piece of a branch and insert it into moist sand and to protect the cutting with a bell-glass to secure a rooted plant; but it is less well known, perhaps, that the last articulation of the branch is capable of making roots much more quickly and readily than those lower down. Mr. Gamble, inspector of the forests of Madras, in south India, tells me that when they desire, in his district, to make plantations of this valuable tree, workmen always take the end of a branch with a single leaf for the cutting, as experience has shown that this is the way to obtain plants quickly and surely, and I believe that horticulturists would do well to follow this plan always in propagating *Ficus elastica*.

This tree, by the way, does not demand a real tropical climate. On the contrary, it flourishes outside the tropics in regions where snow falls sometimes and which experience several degrees of frost. I have seen in the beautiful garden of Hamah, near Algiers, specimens of *Ficus elastica*, and of its relative, *F. Roxburghii*, as large as our large forest-trees, casting a shade blacker and thicker than I have ever seen before. Generally, the genus *Ficus* is hardy and easy to acclimatize.

Ficus australis succeeds admirably in Algiers, and *F. Ben-jamina* is used in the same city as a shade tree in the suburb of Mustapha. There is a large specimen of *Ficus australis*, already old, on the Italian Riviera at Mentone, which, protected on the north by a house, forms a superb mass of dark green foliage; and at Cadiz there is a handsome avenue of large Fig-trees, with small leaves, not far from the Botanic Garden. These are trees two feet or more in diameter of trunk, with thick spreading heads. There are often severe frosts, however, in all these regions.

With regard to the fruit of *Ficus elastica*, I have once seen it on a small plant cultivated in a pot at Bâle, so that it appears that this species bears fruit sometimes in a comparatively young state.

H. Crist.

Bâle, Switzerland.

Winter Protection of Plants in Germany.

To the Editor of GARDEN AND FOREST:

Sir.—An American is surprised to find so many trees, which are quite tender around Boston, hardy in the latitude of Berlin, although the latter city is so many hundred miles further north. Lawson's Cypress and its varieties, Oriental Arbor Vitæ and the various forms of *Retinospora*, for example, seem to be in good condition here, without any protection whatever. So also are the fine specimens of Tree-Box, the foliage of which so often suffers in Massachusetts. The varieties of Ivy show also a marked difference in vigor and hardiness, and are much used as an edging of beds and for low hedging. Probably this difference is caused by the steadiness of the cold here. The sun is so low during the winter months that it has little power, even in the clearest of the short days. As an illustration, a sharp hoar frost on the 10th of November was followed by a beautiful clear day, during which the frost remained all day on the northern slopes of the roofs. The moisture of the air is also a noticeable peculiarity. After several days of steady frost, which permitted skating at Berlin and Dresden on the 17th of November, the moisture had so congealed upon the forests that they appeared to have been visited by a considerable fall of snow.

Undoubtedly the evergreen trees of America suffer from exhaustion caused by the cold, dry winds which sweep through them when the sun runs high, in March. But on the other hand there are many kinds of plants which will not endure this prolonged dampness and freezing of the German climate. Special care is taken for the protection of all such plants. In the gardens of the cities and suburbs, and indeed in the grounds of the nurserymen, the principal material for covering is the boughs of the Norway Spruce. This is regarded as much better than leaves, or anything else that is available. It lies so lightly and is so free from dampness, as compared with leaves, that it is much preferred. And it is laid on with so much neatness and taste as to give the beds the appearance of a plot of living green. The sides of houses, where the *Bignonia* and other vines are trained, are laced up with these boughs so neatly that they seem, at a little distance, covered with Evergreen Ivy.

Our hardy perpetual Roses suffer severely in this climate unless protected, and the boughs prove to be best for this purpose. The bushes are bent and pegged down close to the ground, and are then completely covered with the small branches, usually about two to three feet in length. The systematic trimmings from the forests will, of course, give an unlimited supply of this material, provided the distance of transportation is not too great.

Berlin.

W. C. Strong.

The Cultivation of Chrysanthemums.

To the Editor of GARDEN AND FOREST:

Sir.—Do the best growers of Chrysanthemums agree as to whether it is better to set out the plants in the spring and pot again in September, or to continue the plants right on through the summer in pots?

Why do Chrysanthemums in my greenhouse have a much lighter shade than the same varieties out-of-doors or in some one else's greenhouse? I notice that the Shakespeare, which has considerable pink in its color out-of-doors, is a pure white in the greenhouse with me.

Plainfield, N. J.

C. D. W.

[The practice of the best cultivators is not uniform and fine flowers can be had in either way. The essential point is constant care, so that the plants never suffer from too much water, and on the other hand are never allowed to become dry, nor starved, nor to receive a check in any way. During summer growth the plants may require closer attention if they are in pots; but after all the danger of a check from transplanting is more serious, and most amateurs find it almost impossible to have first-rate, solid flowers by planting in the open ground and lifting in the fall. Plants in the open ground should be potted at the end of August, and a week before they are lifted the roots which extend beyond the dimensions of the pot should be cut off.

Inferior or lighter colors in the flowers may come from starvation, from too much heat, from allowing too many flowers to remain on a plant, or more generally from insufficient light. In any greenhouse, flowers of a pink or lilac shade will be lighter than they are in the open air.—ED.]

A Mild December.

To the Editor of GARDEN AND FOREST:

Sir.—Flowers are opening on *Spiraea Thunbergii* and *Erica carnea*, and buds are ready to burst on *Lonicera fragrantissima*, *L. Standishii* and many other shrubs. On Christmas the thermometer stood at sixty-six degrees in the shade, and a few more days of this weather would force most of our early flowering shrubs into bloom. I hardly dare think of the danger which a sudden change to a zero temperature might cause in the case of many plants, and yet just such a change is likely to happen any day.

Arnold Arboretum.

Jackson Dawson.

To the Editor of GARDEN AND FOREST:

Sir.—Since the 1st of December we have had an unbroken succession of sunny days and frostless nights. The frost in the last days of November nipped the tops of the Scarlet Geraniums, but they have made new shoots several inches long. The Verbenas are still in full beauty; Violets are perfuming the air in all the city yards; Roman Hyacinths have been in bloom outside for over a week; *Lonicera fragrantissima*, which usually blooms on the naked wood in spring, has not yet lost its green summer foliage, but is full of flowers; *Jasminum nudiflorum* is covered with bloom; *Spiraea prunifolia* is in full bloom; *Vinca minor* is covered with blue flowers, and *Solanum Capsicastrum* carries its load of scarlet fruits with no sign of injury.

Raleigh, N. C., December 25th.

W. F. Massey.

To the Editor of GARDEN AND FOREST:

Sir.—Yesterday while passing through the fields I noticed the following plants in flower: *Taraxacum Dens-leonis*, *Maruta Cotula*, *Capsella Bursa-pastoris*, *Polygonum aviculare*, var. *erectum*, *Stellaria media*, *Cerastium vulgatum*, *Poa annua*.

Excepting the first, these all grow on low moist ground, and within a few feet of each other. Besides these, I found *Malva Rotundifolia* well budded, and the trailing *Arbutus* and *Hepatica triloba* with buds almost ready to open.

Youngstown, O., December 19th.

R. H. Ingraham.

Periodical Literature.

Mr. Edward L. Greene prints in his *Pittonia*, under date of December 10th, of which advance sheets have reached us, an interesting paper on the North American *Neillia*, which he retains in *Neillia*, published by Don in 1825, discarding the later *Physocarpa* of Rafinesque, adopted by Maximowicz, the last author to study critically the *Spirææ*. Mr. Greene points out that the leaves upon vigorous shoots are rarely found in her-

bariums, although they often afford valuable characters, being really the normal or typical leaves, while the flowering and fruiting branches usually collected are in reality nothing more than leafy peduncles, on which the leaves are greatly reduced generally in size and often altered in shape, a fact which is equally applicable to the true *Spirææ*s. Mr. Greene increases the number of American species of *Neillia* from two to four. The Pacific Coast plant, first described by Pursh as *Spiræa capitata*, which has been included by most botanists with the eastern *N. opulifolia*, is now considered a species under the name of *N. capitata*, the shape of the slenderly and obliquely pyriform seed being depended on to distinguish it. It is a widely distributed shrub west of the Sierras and Cascade Mountains, growing sometimes to a height of twenty-five feet, and extremely variable in the character of its pubescence. *Neillia Torreyi* becomes *N. monagyna*, this being the earliest specific name applied by Torrey to the species then thought to belong to *Spiræa*. The figure (the only one) published in GARDEN AND FOREST, ii., p. 5, is overlooked.

A fourth species, *N. malvacea*, discovered by Mr. Greene on the northern shore of Lake Pend d'Oreille, in northern Idaho, is here first described in a section created to receive it, and characterized by "carpels not inflated, included in the calyx, erect and straight at apex, indehiscent." The leaves are digitately five-veined, and often broadest above the middle. To this species Mr. Greene suggests that many specimens from Nevada, Utah and Montana referred to *N. monagyna* really belong.

Recent Publications.

Aspects of the Earth; A Popular Account of Some Familiar Geological Phenomena. By N. S. Shaler, Professor of Geology in Harvard University. Illustrated. New York: Charles Scribner's Sons. 1889. \$4.

A real service has been done the public by the issue in book form of the clear, trustworthy and interesting essays on various groups of terrestrial phenomena which Mr. Shaler first printed in *Scribner's Magazine*. They now form a connected treatise of much greater utility than its title suggests; for not only the present aspect but the past history of the earth is made plain, and from the data thus supplied prophecies are drawn which every man who owns an acre of ground or has a hand in legislation should study as guides for immediate action.

"The Stability of the Earth," "Volcanoes," "Caverns and Cavern Life," "The Instability of the Atmosphere," "The Forests of North America" and "The Origin and Nature of Soils" are successively discussed, man's relation to the world, thus explained, not being for a moment lost to sight. The practical character of the book is, indeed, its most distinctive merit. The chief fact it leaves impressed on the mind is the immeasurable importance of our forests from an economic and sanitary as well as scientific point of view. This could not have been more truthfully or lucidly set forth, nor could there have been a better moment for such an explanation. It ought to prove an efficient antidote to certain mistaken theories with regard to deforestation that have recently been promulgated, as it shows not merely how our water supply, but how our soils, vegetation and atmospheric conditions must be affected by the destruction of our forests. If it wins the popularity that seems in store for it, a great increase of national conscientiousness as regards forest legislation ought to be the result. Many of the points it emphasizes have often been brought forward in these columns; but as marshaled and commented upon by Mr. Shaler they will make a fresh impression even upon the most earnest and loyal of our readers.

Perhaps the most interesting chapter, because the most novel (it is the only one that has not appeared in *Scribner's Magazine*), will be the final one, on "Soils." Even those who know how likely the world is to be deprived within a calculable space of time of its carboniferous and metallic deposits and of its arboreal garment, seldom realize that it is in danger of losing the greater part of that layer of disintegrated rock and decomposed vegetable matter which we call soil. Fancy a world deprived of arable ground and we see a world in which man could not live. The lack of coal and metals he will probably be able to make good in other ways; the lack of forests might be repaired by a very slow process were the soil preserved; but the lack of soil itself could be overcome only by a process as inconceivably long as that which has put the earth in the condition in which we see it now. Yet only one-fifth of the arable lands of the world, as Mr. Shaler computes, are practically safe; four-fifths are in great danger, not only from deforestation, but from the agricultural methods now in use.

So great, indeed, is their danger, that Mr. Shaler considers the soil problem "perhaps the most serious of all the physical difficulties which beset the future of man." What is needed now is forest legislation, accompanied by a wise system of irrigation. What will eventually be needed is legislation to regulate even agricultural processes as simple and apparently innocuous as the annual overturning of the surface of a field by the plow. We must husband our water, we must husband our trees, and we must husband our precious layer of plant-feeding earth if future generations are to be fed at all. The great merit of the present book is that it shows not only the necessity of each of these efforts, but the vital interdependence of each upon the others.

Very charming reading is the passage (beginning on p. 268) where a virgin forest is described, the text being that great Appalachian forest of ours where "are still to be found, perhaps, the finest areas of virgin woods of the deciduous type that remain upon the earth;" where the trees "are of exceeding variety and man has as yet spared them the destruction which he is soon to inflict."

Except for the ill-drawn and ugly figure on the cover, the "Aspects of the Earth" is an excellent piece of book-making, and its illustrations are as illuminative as attractive. Mr. Shaler is too modest when he says that from the point of view of instruction they are the most valuable part of the volume; but they are worthy to accompany his text, and this is high praise. We have felt it a duty as well as a pleasure to call attention to a book which will interest every man who cares to look at the world he lives in, and will wake the conscience of all who feel they owe a duty to posterity.

Notes.

The original appropriation for parks and gardens, in connection with the Paris Exhibition, was 3,082,654 francs, or more than \$600,000.

According to the San Francisco *Examiner*, Mr. Adolph Suto is experimenting with Cinchona-trees on his estate on the neighboring sea-coast. He hopes to acclimatize at least some of the varieties from which quinine is produced; and if so, will doubtless be more than repaid for his enterprise.

We have received the July, August and September numbers of the Journal of the Japanese Horticultural Society. The first contains an excellent colored plate of *Eriobotrya Japonica*, showing a large, distinctly pear-shaped fruit, a form which does not occur on the plants cultivated usually in our southern states.

The prices recently quoted in the newspapers as asked for Christmas-trees in New York refer to the down-town markets, and give no real idea of those paid by purchasers up-town. In the vicinity of Jefferson Market from \$2 to \$4 were asked for good specimens not more than nine feet tall, and \$25 were demanded for the finest and largest trees, which reached thirty-five or forty feet in height.

Mr. Jackson Dawson observes that the fruit of *Berberis Thunbergii* is much relished by quail, although the birds do not eat the entire berry, but pick out the seeds only from their scarlet covering. This suggests the idea that this Barberry would be a good shrub to plant for game covers. The berries remain on the bushes all winter, and they might make excellent food in a season when little else could be found.

A correspondent of the *Journal des Roses* recently recounted an experiment he had made to test the influence of the stock on grafted Roses. Two lots of Roses, one grafted on *Rosa canina* and the other on *R. polyantha*, were forced under glass, both being treated in precisely the same manner. The flowers which stood on *R. polyantha* came into bloom two weeks earlier than the others and yielded twice as many flowers.

M. Von Volxem, the distinguished Belgian dendrologist, referring, in a private note, to our article on *Acanthopanax ricinifolia*, published on page 568 of volume ii., reports that this tree is hardy in Belgium, but grows so slowly that his plants are only a foot high at three years of age, in good soil; another instance to be added to many already known of east Asia deciduous plants growing better in eastern North America than in northern Europe.

A noticeable feature of the Christmas flower trade in Boston was that large, showy flowers were not sought for. Harris' Lilies and Callas found few buyers at any price, while long-stemmed Carnations, particularly flowers of the Grace

Wilder, were in great demand. The sales of "Christmas green" were larger than usual, and among the various kinds used there appeared limited quantities of the evergreen *Euonymus Japonicus* in fruit.

A Philadelphia correspondent writes that there is more call for American Beauty Roses than ever before, but even at high prices it is rarely a profitable variety to the grower. The Wootton has not been able to displace it in popular favor; but as the newer Rose is more profitable for growers, even at lower prices, it will force its way in the market. The Duchess of Albany, with its beautiful fresh color, is rapidly gaining favor, and buyers are already inquiring for Madame Hoste. Its delicate yellow shade and perfect shape recommend it to every lover of Roses.

The tops of young southern Pines (*Pinus palustris*), from Georgia or Florida, were conspicuous objects in the shops of New York florists last week. Stems of young, vigorous saplings four or five feet long, with the terminal cluster of leaves, are cut and stuck into flower pots filled with earth. As the leaves remain fresh for a considerable time, the cut stem has every appearance of a living plant. The long, bright green leaves and the white scales of the large terminal bud, which are peculiar to this tree, make the young plants ornamental and attractive objects, well suited for the decoration of churches, for which they are used principally in this city, or other large buildings.

The three Grand Prizes awarded at the Paris Exhibition for information with regard to "Useful and Destructive Insects" fell to Professor C. V. Riley and to the Agricultural Departments of the United States and Japan. Of the seven Grand Prizes awarded in the Section of Agronomy and Agricultural Statistics two fell to the United States Government and the Ministry of Public Works of Mexico. No Grand Prize for wine or viticulture was awarded to an American, but one firm in the United States received this recompense for beer. Eight such prizes were given for machines and processes connected with work in farm and forest (*Materiel et procédés des exploitations rurales et forestières*), and of these, two were gained by Americans—by Walter A. Wood and the McCormicks.

Dr. James C. White, of Harvard University, reports in the Boston *Medical and Surgical Journal* an interesting case of *dermatitis venenata* resulting from the use of the Garden Box. The patient was a young woman suffering from an attack of acute inflammation of the face, which was uniformly and greatly swollen, presenting generally the appearance of Rhus or Ivy poisoning. She had, it appeared, made a decoction of Garden Box and applied it to her scalp for the purpose of preventing her hair from falling out, and the liquid had run down over the face, which she had subsequently washed with the rag used in applying the liquid to the scalp. The inflammation, in spite of local treatment, had not disappeared at the end of six or seven days from the time of the application. Dr. White, who is a distinguished authority on *dermatitis venenata*, remarks that this is the first case of poisoning by Box which has come under his observation, although the poisonous properties of the plant have been suspected for many centuries, as it belongs to a family containing violent and cutaneous irritants, such as croton oil, manchineel stillingia, and the oils of *Fathorpha urens* and *Hura crepitans*.

The "flower festivals" of the Japanese are often referred to without clear explanation of their number and character. Five are annually celebrated. At the New Year's Feast, on the first day of the first month, the chief plants used are Bamboos, Firs, *Prunus Mume* and *Adonis Amurensis*. The first two are set by the house-door, and the others are displayed in the living-room. At the second, or "Girls' Festival," which is held on the third day of the third month, *Prunus Persica* is the favorite plant. At the third, or "Boys' Festival," on the fifth day of the fifth month, one sees chiefly the Shobu (*Iris laevigata*); while at the fourth, or "Ladies' Festival," on the seventh day of the seventh month, no flowers are favored, but songs are written on bits of paper fastened to leafy stalks of Bamboo and set on high in the garden. The last feast occurs on the ninth day of the ninth month, and then the Chrysanthemum is honored by old and young alike. These various celebrations have always been held in accordance with the dates of the old national calendar; but now that the Gregorian calendar has been introduced, it is found difficult to procure the proper plants on the proper day. The great imperial feast in honor of the Chrysanthemum has no special time set for it, but is held whenever the flowers in the Emperor's garden are in most perfect condition.

The Forests on the Public Domain.

THE address by Major J. W. Powell, Director of the United States Geological Survey, before the Chamber of Commerce of this city, on December 5th, on "Problems of Irrigation," was an eloquent and suggestive discourse. He explained that there are nearly a thousand million acres of arid lands in the United States, or one-half of the area of the country, excluding Alaska. Nearly one hundred and twenty million acres can be irrigated when all the available water is used. More than six million acres are already cultivated by means of canals. The great resource for irrigation is the use of the rivers, and accumulated capital and organized industry are necessary for the construction of reservoirs and other works required. "Capital must come, for the work is demanded and will pay." He thinks it will cost about ten dollars an acre to redeem the arid land, and fifty dollars an acre he regards as a small estimate of its value after it is put under irrigation, and thus the investment of a thousand millions of dollars will yield five times that sum by the redemption of a hundred millions of acres. Where agriculture depends upon irrigation, if there is more land than the water will supply, values inhere in water, not in land, as land without water is without value.

The arid land, he said, is now mostly in the possession of the general Government, and it is important to determine how the water shall be divided. When all the water of the Arkansas River is utilized it will irrigate only about one-third of the land of the valley. The people of Kansas want this water, and say it should be left in the river channel till it runs down to them, and they are using some of it, and the people of Colorado have taken a large part of it out on their lands. When seasons of drought come they permit no water to flow across the state line, and the agricultural property below is threatened with destruction. If every man may take out water as he pleases, the men along the river below are at the mercy of those above them. This is an inter-state problem to be settled by the general Government. Already there is conflict between farmer and farmer, between different counties and between states.

In Major Powell's judgment, the foot of the steep slopes, the point at which the river enters the plain, is the place at

which the water should be taken from the river channel for irrigation. If permitted to flow farther down much of it will be lost by evaporation, and it will take up mud which will choke the reservoirs. The general Government should determine where these waters are to be used, and should exercise supervision in this matter when it disposes of its lands to actual settlers, taking into account the welfare of the greatest number of people yet to find homes. Montana and the two Dakotas are interested in the water of the upper Missouri, and there is not enough for all the arid land of the valley. How shall it be divided? The Rio Grande del Norte is, in a part of its course, the boundary between this country and Mexico. The division of its water is an international question.

We quote from a noticeable passage on mountain forests:

"On the mountains and plateaus of the arid lands great forests are found. To a large extent they are composed of coniferous trees—Pines, Firs, Hemlocks and Sequoias. The plains and valleys below, where agriculture by irrigation is to be carried on, are treeless and almost naked of grass. The forests flourish where the rains fall in the regions above, but these forest lands are not agricultural for climatic reasons, as snow and frosts prevent farming in those regions. It is thus that the forest lands and the agricultural lands are severed. They are often far away from each other—tens, scores and hundreds of miles apart. The people below on their farms, and in their villages and cities, require this timber for their domestic use, and they are the people primarily interested. But these farmers have still other interests in the forest lands. The mountains where the forests grow are the catchment areas for the waters which they must use, and, to a large extent, the mountain lakes are natural reservoirs for the waters of irrigation, and many of the mountain valleys must be converted into reservoir lakes by the hand of man. So the management of these forests and forest lands should be in the hands of the men who use the timber and who must control the waters. If they are unwisely destroyed, the sources of water supply are impaired. Consider how these forests are destroyed. More than two decades ago I was camped in the Middle Park, of Colorado. The night was arched with the gloom of snow clouds, so I kindled a fire at the trunk of a great Pine, and in the chill of the evening I gazed at its welcome flames. Soon I saw it mount, climbing the trunk, crawling among the branches, igniting the rough bark, kindling the cones and setting fire to the needles, until in a few minutes the great forest Pine was all one pyramid of flame, which illuminated a temple in the wilderness domed by a starless night. Soon the fire flakes were borne by the winds to other trees, and the forest was ablaze. On it spread with the winds, and the lingering storm came not to extinguish it. Still on it swept for miles and scores of miles, until more timber was destroyed than has been used by the people of Colorado for the last ten years. It is thus that, under conditions of civilization, the great forests of the arid lands are being swept from the mountains and plateaus.

"The people of this country, witnessing this vast destruction of values and the deterioration of the water sources of arid lands, are appealing to the general Government for a Forestry Commission—the establishment by law of armies of men to protect the forests, and they propose that the general Government shall engage in timber culture and in the timber business, holding the lands in the possession of the Government and selling the timber to the people who live below. For this purpose thousands and scores of thousands of men will be needed, a formidable list of offices must be created, and office-holders multiplied.

"The great forests that clothe the hills, plateaus and mountains with verdure must be protected from devastation by fire and preserved for the use of man, that farms may be protected and homes built; and that all this wealth of forestry, those unborn cottages and school-houses may be distributed among the people."

How is all this to be provided for? Major Powell says to the general Government, "Hands off!" He would organize the people of each river drainage area, or hydrographic basin, into a great irrigation district, under national and state laws, and then let them make their own laws for the division of the water, for the protection and use of the forests, for the protection of the pasturage on the hills, and for the use of the water-power:

"This, then, is the proposition I make: That the entire arid region be organized into natural hydrographic districts,

each one to be a kingdom within itself, for the purpose of controlling and using the great values which have been pointed out. . . . The plan is to establish local self-government by hydraulic basins, and each basin may constitute a great country. Some great river basins would have to be divided into two or more districts. . . . Let the people of the district provide their own officers for the management and control of the water, for the protection and utilization of the forests, for the protection and management of the pasturage, and for the use of the power, and with district courts, water-masters, herders and foresters, they would be equipped with the local officers necessary for the protection of their own property and the maintenance of individual rights. The people of each little kingdom, or separate hydraulic basin, can obtain capital by their own enterprise as a community. Constituting a body corporate, they can tax themselves and can borrow money. For security they have a basis of land titles, water rights, pasturage rights, forest rights and power rights."

But now comes a curious proposition:

"Let the general Government make a survey of the lands, segregate and designate the irrigable lands, the timber lands, the pasturage lands and the mining lands; then let the general Government retain possession of all but the irrigable lands, but give these to the people as homesteads. Then let the general Government declare and provide by statute that the people of each district may control and use the timber, the pasturage and the water-powers under specific laws enacted by themselves and by the states to which they belong."

What would be the advantages of having the nation retain possession, in name only, of the mountain forest-lands if the people of the valley are to control and use the timber on the nation's lands as they please, without supervision by the national Government, and without any responsibility to national authority? If the nation is to "retain possession" of the forests, it should have some control of its own property. On the other hand, if the people of each irrigation district are to have entire control of the mountain forests about the sources of the streams, the nation's title should be extinguished and the forests should be owned by those who are to have complete control of them. It would then be easier to educate the owners in sound ideas regarding the functions and value of the forests, and there would be more chance of their some time learning to take care of them. At present millions of people have a special appetite for pillaging public property, and if the forests belonging to the nation are to be left without defense to the uncivilized impulse and caprice of the new communities, there should be no pretense that the nation retains possession, as under the proposed system it would have no power or right to defend or protect this invaluable forest property. Responsibility should rightly go with control, and if the local community is to have complete control, its responsibility for the fate of the forests should be brought home to it in the plainest possible way.

What is really desired by intelligent men who are interested in the relations of the forests on the public domain to the national welfare is that the nation shall examine its magnificent forest property, and ascertain its character and extent before making any final disposition of it. Why should the Director of the National Geological Survey oppose the appointment of a competent commission to make such an examination? The country would not be obliged to adopt any recommendation of the commission, but the knowledge obtained by its investigations would be the best preparation and basis for right action. The facts regarding the forests on the public lands which the officers of the Geological Survey have been able to observe during their absorbing labors in their own field are highly interesting and valuable; but there has been no adequate examination of this important national property. Until such an investigation has been made, and the facts have been placed before the people of the country, no settled or final policy regarding these forests can be intelligently adopted.

In this important address the fundamental truth that the forests which are the subject of discussion are the property of the nation, of all the people of the United States, is recog-

nized indeed, but without developing it, or indicating its relations to national responsibility. It is most important that we should properly estimate the opportunity which national ownership presents for surrounding this invaluable national property with such safeguards as may appear judicious or practicable when we have ascertained what our heritage is. The forests and the lands of the public domain belong to the people of this state as much as to any other local community. The nation holds this vast wealth in trust for future generations. It should ascertain its nature and extent, and then determine wisely what arrangements will be best adapted for its permanent administration.

Down the Rhone.—I.

NORMANDY, Brittany and the coast near Nice are familiar parts of France to the American tourist, and the Loire Valley, like Picardy in the north-east and a portion of the Pyrenean region in the south-west, are not unknown to him. But who travels in the great central district that stretches from the Bay of Biscay to the German frontier, and from the shores of the Loire to the skirts of the Pyrenees? It is incomparably beautiful, all this great stretch ignored of the foreigner, and its beauty varies strangely with every journey one may make—changing from volcanic majesty to pastoral loveliness, from a rocky, wooded picturesqueness to the southern charm of wide green plains, set about with naked masses of yellow hills. But no part is more delightful than the valley of the lower Rhone, and this is the very part that is most seldom seen. Of course the Rhone Valley is constantly traversed by rail, but the journey is usually made in winter, and even in summer one cannot really see it from the train—not even so well as one can see the Rhine; for the road seldom keeps close to the bank, and often one would not guess the great river's existence.

Fortunately, before we started on a long French journey last summer, we fell in with certain artists who had once gone down the Rhone in the proper way by accident—for cheapness' sake, uninformed of all the increase of delight that the diminution of expense would mean—and who had since gone about, usually in vain, trying to persuade others to do the like. So we found ourselves in the middle of July starting on a Rhone voyage from Vienne, a little way below Lyons. Vienne itself is well worth seeing. It is perched on the high eastern bank, and has crooked old streets, quaint little churches, Roman ruins, and a cathedral whose façade has been eaten by centuries of river breezes almost into the likeness of a sponge, but is still superbly effective at the top of a stately terraced stair. The drives along the river are enchanting, too. When the boat, which starts from Lyons an hour earlier, swept into view at 8 A. M., we saw a long, narrow steamer, piled high with freight, and full amidships and at the stern with peasants going short distances down the stream. No one travels here for the sake of traveling—the only purpose of the boat is to serve local traffic—so that stops are made at every village. But this fact merely adds to the interest of the trip, and it means, furthermore, that one has to one's self the space in the bow which is reserved for possible first-class fares. We were all alone on our July day, except for a single Frenchman who was showing his daughter the river, on one of their frequent visits to their family in the south; and does this not sound pleasant to the reader who knows what the tourist crowd on a Rhine steamer means?

Yet the Rhone, if one could not see both, is better worth seeing than the Rhine, and not merely because one is proud to be "doing" something that all the world has not "done" before him. The glimpse of its beauty which we had while driving about near Vienne almost persuaded us to think as much, and the further we went, the more we believed it. Do you fancy the landscape flat and monotonous? There is no place between Lyons and Avignon where mountains are out of sight, or where there is more flat land than serves to make beautiful fertile plains in admirable contrast with the rocky yellow hills that encircle them. Are there ruins and picturesque churches all along the Rhine? So there are here, in even greater numbers, in much greater variety. Do you delight in picturesque villages? You have never seen them till you have seen what they mean on the Rhone. If there are no crags so bold and rocky as one sees in the Lorelei region of the Rhine, there is an endless succession of superb rock-forms more suave in contour, far more lovely in color—yellow almost always, touched with spots of dusky foliage, and passing into the softest tones of white and gray. Then,

between the rivers as such there can be no comparison. The Rhine seems a poor stream contrasted with this wide, arrowy Rhone, so full that it has to be dyked in here and there with masonry, and that even in midsummer the water rushes up close to the top of the embankment; so swift in its fullness that the boat's speed is most exciting, and when we pass beneath a bridge there is a roar like that of a cataract; the most charming color, too—a sort of pale greenish gray that turns all sorts of tints with the varying light, and seems to breathe the coolness of the distant, perennially feeding glacier. For form one may easily prefer the Rhone landscape to the Rhine landscape; in color it is immeasurably ahead; and if its historic interest seems less, this is only because we are as oddly ignorant of French history as of the aspect of France. Speaking materially, too, this voyage is the more delightful. The mere absence of tourists means great comfort for body and mind, and even on this little provincial boat French skill provides food for the daintiest palate. The weather may be hot sometimes, but hardly as Americans use the word; and on our July day it chanced to be too cold in the morning, and even when we got far south was rather cool than warm. But what seems to me the very best thing about the Rhone remains to be told. It does not always show us varying forms of the same type of landscape, but takes us from what is almost the north into what is truly the south. As we watch its banks we see the character of land and vegetation changing; architectural features lose their northern and take on their southern shape; the light grows clearer and stronger; color gets ever more and more intense. We start at Lyons and we end at Avignon, and there is almost as much difference in the names as though we had said bluntly "North" and "South," and, again, as though we had said the modern and the mediæval world.

As we left Vienne there was just behind us the great bridge which connects it with the picturesque suburb of St. Colombe; the shore was fringed with scattered factories, looking not unpicturesque amid groves of tall Poplars and against a background of hills delicately tinted by the misty morning light; and, in front of us, under great banks of gray cloud, there looked to be no river, but a great lake, for there is a bend to the westward about a mile away, and hills of beautiful outline stretch across the southern sky and hide the course of the water. But as we rushed off to the right—getting our first taste of the motion, which is sometimes a rush, sometimes a long, smooth, swallow flight and sometimes a swirl that feels like incipient shipwreck—our course opened out again, with a bit of flat land on the left and rounded hills on the right, with densely wooded hollows between them. Quickly we take an abrupt turn in the opposite direction, and the stream seems blocked again by a low hill at the foot of which four giant Poplars stand up above their fellows like giants to take toll. Then on the west, as we round the point, is the village of Condrieu, where we make our first stop. The boat is warped up to the high water-wall only by all the force of reversed engines and scores of sturdy arms, so relentless is the rush of the river. Every such stop is a new excitement—much cheerful noise on shore and the feeling on board that the boat will never be brought to its place.

Condrieu is very picturesque, the low, tiled houses, whose stones show through the thin, brownish-white plaster crowding close on top of the wall, with vine-clad loggias and masses of pink and white Oleanders between them. The roofs are dull brown, and the cornices of that simple, cheap yet effective kind which is common all through central and southern France. Several rows of concave tiles are laid with the hollow side down, each row projecting beyond the one beneath it, and the interstices filled with plaster, against which the tiles show in pretty scalloped lines. Here, too, we saw our first Fig-trees, while Mulberries abounded, and back of the village were endless rows and groups of slender Black Poplars, with an occasional more massive Lombardy. Lindens and Horse-Chestnuts clothed the outskirts, and just below the town the hills were covered with vineyards. The river winds continually below Condrieu, showing us blue mountains far off to the west, and here and there a square church tower that seems as appropriate to the landscape as does the spire in Normandy. Stone dykes are frequent and not only in the neighborhood of the towns; and where there is no dyke, Poplars and Willows come close to the edge. Near St. Pierre-de-Bœuf is a light suspension bridge—I think the one that Dumas speaks of in his "Voyage dans le Midi de la France" as the first that had been built in the country. Flat, fertile plains occur, but always bordered by hills, and I remember one little town where a rough stone church had buttresses and capitals of white stone or marble, adding the gayest of notes to the picture. Pollard Mulberries run in long lines between the fields, and some-

times the near hills lie in low, gentle waves like sea water charmed to rest. It is all incomparably picturesque—not with the jagged, irregular picturesqueness we know in the north, but with a suave and gentle modulation that, perhaps, better deserves the term pictorial. The Rhine may more greatly attract an uneducated eye—there is no artist who would not prefer the softer majesty of the Rhone shore. Harmony is the word that always comes to mind—never a discordant line, never a crude tint, yet what variety in line, what warmth and richness of color! When the clouds veil the sun a little and Poplars and Willows are most numerous and come closest to the stream, one gets a succession of "Corots" as complete and exquisite as ever came from the master's brush. Perhaps one of the most charming forms the shore assumes is when rather steep yet rounded hills lie with their deep yet gentle valleys at right angles to the stream, and, while the hills are clothed with vineyards or dotted with low, gray shrubs, the vales are filled with forest.

At Serrières is a new stone bridge with one of its piers, something like a Brooklyn bridge pier on a smaller scale, set close against the flank of a high green hill. The water-wall is in two high terraces, and some of the houses have a strangely military look, being formed of two round towers with a "curtain" of wall between, their brownish stone and stucco coming out effectively over the Corot-like foreground of pale gray water and foliage. Near Sarras the hills were high, close to the stream and uncultivated, the rocks cropping through their flanks amid a scattering of grass and low brush. There is a bridge with three towers here, and factories of rough stone with brick trimmings, ugly, yet not actually distressing to the eye. Beyond the town, on the naked hill-tops, were three "calvaries," or great crucifixes for way-side prayer, gilded and shining from afar. Then came cultivated hills again, varied by broad patches of rough soil; and soil and houses together grew yellower and yellower, and spoke more and more plainly of the coming south.

M. G. Van Rensselaer.

Holiday Notes in Southern France and Northern Italy.—X.

A few miles westward of Mentone, on a coast abounding in sites of matchless beauty, we come to Monaco, the capital of a principality interesting from many points of view, historically and otherwise; in size, however, the entire realm is less than many and many an English parish. The mountains protecting the coasts from the chilling northern blasts are only of moderate height, but are very picturesque, and their proximity adds another charm to Monaco, the beauty-spot of the Riviera. The gardens of Monte Carlo have been frequently described in horticultural journals—British and continental—but they contain so many objects of interest to the botanist and gardener and furnish such a series of contrasts and surprises that accounts of them have not yet ceased to charm the plant lover. Fancy the sensation of a northern gardener on seeing, side by side with the common Weeping Willow, big bushes of *Datura* (*Brugmansia*) *suaveolens* laden with their large white trumpets; then the Bougainvillea and the Cherry Laurel—perhaps the most widely planted evergreen in the British Islands—the scarlet-flowered *Tecoma Capensis* and some hardy Silver Fir. Examples of shrubs, etc., hardy in Britain and the northern United States, luxuriating with denizens of tropical countries which we had never seen previously except under glass, are too numerous to mention.

Untraveled readers who can refer to the *Gardeners' Chronicle* for 1874 are invited to turn to pages 820 and 821; there they will find an excellent illustration of the town of Monaco and another of a view in the gardens at Monte Carlo. The capital of the little principality is perched on a precipitous mass of rock which juts out into the Mediterranean. Scarcely a greater contrast can exist than that between the garden of the last-named city and the one in the neighborhood of the Casino at Monte Carlo; in the former case there is an absence of anything savoring much of artificiality—walks wind about under the shadow of the Pines (*P. Halepensis*), while Agaves and Opuntias, Mesembryanthemums and other succulents have thoroughly naturalized themselves, particularly on the seaward side, where they brave the sea breezes in spots inaccessible even to goats. The beauty of the scene here was not lost on Prince Florestan, who describes "the tall Palms, the giant Tree-Geraniums (Pelargoniums) blooming in masses down the great cliffs to the very edge of the dark blue sea, the feathery Mimosas (Acacias), the graceful Pepper-tree (Schinus), laden with crimson berries, the Orange-grove, the Bananas fruiting and flowering at the same time, the Passion-flowers climbing against the rugged old castle walls, etc."

The underwood beneath the Pines is almost entirely composed of scarlet Pelargoniums—great bushes three or four feet high—masses of bloom and growing as freely as brambles in a thicket; not even at the Cape of Good Hope can they be more luxuriant or splendid.

In the old garden nature has done much and art comparatively little; in the Monte Carlo garden the aid of the landscape gardener has been invoked, and to some purpose too. Near the Casino itself stately terraces have been made in harmony with the lines of the building erected nearly ten years ago by Garnier, the architect of the new Paris opera house. At the same time Monsieur Edouard André remodelled all the gardens, which are now said to be amongst the most beautiful in the world. The combined attractions of roulette, the lovely site and gardens and excellent music—the orchestra is world-renowned—render Monte Carlo a very popular resort, and the extensive additions, on which an army of men were employed, did not, on the part of Monsieur Blanc, seem to indicate much fear that the opponents of gambling would soon succeed in their efforts to get the tables suppressed.

Of course Palms play a great part in the Monte Carlo landscape; the Date-Palm attains a large size, so does the Chusan Fan-Palm (*Trachycarpus* [*Chamerops*] *excelsus*). The Mediterranean Fan-Palm (*Chamerops humilis*) is useful for massing, and varies greatly in size, length of leaf-stalk, the character of the spines thereon, etc. During winter its mass of orange colored fruits form a dense collar round the stem at the base of the crown and produce a fine effect. *Washingtonia filifera* is abundant, and the Silver Palm—*Erythraea armata*, or, as it is everywhere called along the Riviera, *Brahea Ræzii*—a Mexican species, makes a most beautiful object; it is, however, usually grown as a single specimen on lawns, not yet being common enough to plant in groups. *Cocos flexuosa*, very fine plants, some thirty feet high, with their splendid plume-like leaves and smooth stems, make a most attractive feature. *C. Fatai* and *C. Blumenavii* are two of the many names under which the Brazilian *C. capitata* is grown. Sabals exist too under garden names, and Palm nomenclature along the Riviera is, on the whole, in a very sorry state. It is quite impossible to clear up the confusion surrounding the genera Phoenix, Cocos, Sabal and others unless some careful observer studies all the so-called species in a living state under conditions favorable to their development; and for this many spots along the Riviera supply a suitable environment.

Cycads are not strongly represented at Monte Carlo. There is on one of the lawns a fine *Dioon edule*, and elsewhere a big specimen of the Caffer Bread, *Encephalartos Caffer*. *Cycas revoluta* was the member of this family most frequently met with both here and elsewhere. Bamboo-groups produce beautiful effects; many species of these noble grasses exist under garden names only, and until they flower it is impossible, in many cases, to determine with certainty even the genera to which they belong. Some of the Bamboo-masses had a forest of stems thirty feet high or more.

One pretty effect was produced by a Pine heavily draped with the small-leaved climbing Polygonaceous plant (*Muehlenbeckia complexa*). In the same way *Trachelospermum* (*Rhynchospermum*) *jasminoides* was used to clothe the stems of large Date Palms. *Phytolacca dioica* here makes a tree in a remarkably short time, and is effective enough. A few years ago a Cape dealer made a good hit—from his point of view only—by selling young plants of this, as a timber tree of wonderfully quick growth, to the south African-colonists. The India rubber-tree (*Ficus elastica*) makes a huge specimen at Monte Carlo and develops adventitious roots quite in a tropical manner; the Australian *F. macrophylla* does equally well. One of the handsomest flowering plants I saw was a Solanum called *S. Rantonetii*, a species with round, shallow, saucer-shaped flowers, with deep violet flowers and golden anthers; and *S. glaucum*, a dozen feet in height, was also finely in flower.

Grevillea robusta, so much used in a small state for room and conservatory decoration in England, here makes a good tree. Of course the names of a large number of plants previously noted by me in these columns are not repeated here, and unfortunately, lack of space prevents my dwelling longer on Monte Carlo.

At the beginning of September the bush Roses had all been cut back and some had already broken. The ground at the same date had been roughly turned up previous to raking and leveling, treading firm, etc., and sowing with English Ryegrass; in this hot, dry region it is next to impossible to keep grass alive, and it is only where labor and water supply are abundantly and constantly employed that lawns can be kept

green during the summer and autumn months. The general practice is to sow them annually.

La Condamine, on the little plain between the promontories of Monaco and Monte Carlo, connected with both places by splendid roads, can boast of a very fine line of *Nerium Oleander*, the large double-flowered form. The trees have clean stems of six or seven feet, and good heads, which were covered with blossoms at the time of our visit.

Kew.

George Nicholson.

New or Little Known Plants.

Hydrangea vestita, var. pubescens.*

THIS Hydrangea (Fig. 3, p. 17 of this issue) is one of the handsomest of the numerous shrubs which have found their way of late years from China and from Japan into our gardens. A native of the mountains of northern China and of Mongolia, it is not believed by M. Maximowicz to be specifically distinct from the Himalayan *H. vestita*, a small tree, of rather wide distribution. Here the north China plant makes a graceful shrub, four or five feet high, with slender branches covered with red-brown bark. The leaves are pale green and rather velvety on the upper surface, ovate-acute at both ends, or sometimes somewhat rounded at the base, coarsely glandular-serrate, three and a half to four inches long, borne on stout petioles, cinereous-pubescent, and slightly rugose on the lower surface, as are the young shoots, the petioles and the inflorescence.

The cyme of flowers is flat and ample, with numerous neutral ray flowers an inch or more across when expanded. These open early in July, and are then creamy white; they gradually change to rose color, and remain quite fresh upon the plants until November.

This plant is perfectly hardy. It is the first of the Hydrangeas to flower, and the most desirable as a garden-plant of all the species which are hardy in this climate, with the single exception of the Oak-leaved Hydrangea (*H. quercifolia*) of our south Atlantic States.

The specimens in the Arboretum were raised from seed sent several years ago from Pekin by Dr. Bretschneider, to whom we are indebted for a number of fine hardy plants.

Foreign Correspondence.

The New Plants of 1889.—I.

THE new plants introduced into English gardens during the present year are few when compared with the record for previous years. This is the more surprising when we recollect that many more collectors are at work now than ever before. Apparently these men are engaged in collecting and dispatching to England large quantities of standard or favorite plants, chiefly Orchids, for which there is a large and constant demand. Few nurserymen, including even those who, until recently, were identified with new plants of all kinds, appear to pay much attention to the introduction of anything except Orchids. Now and then a good plant finds its way to England to be taken care of and afterward distributed, but this appears to be oftener the result of accident than of design.

The botanical explorations of such men as Dr. Henry in northern China, the Abbé David in northern China and Mongolia, and the Abbé Delavay in the western province of Yun-nan have resulted in the addition of a few good plants to our gardens, of which more will be heard in the course of time; but these are mere scraps as compared with the riches revealed in their botanical collections. The preparation, packing and trouble necessarily attendant on the safe introduction of living plants into Europe from such countries as those named must deter many from attempting it, and yet to any one acquainted with the many means, such as seeds, bulbs, tubers, etc., at the disposal of those who are in unknown regions, the pity of missing the opportunity is great. Even such a journey as that recently accomplished by Mr. Stanley must have afforded a splendid chance for a collector with his wits about him. That a great deal can be done at such times has been proved again and again, notably by Dr. Aitchison when with the Afghan Boundary Commission, and before that, during the Afghan war; for, notwithstanding his official work, the energetic doctor collected

* HYDRANGEA VESTITA, var. PUBESCENS, Maximowicz, Mem. Acad. Sci., St. Pétersbourg, 7 série, x., 10.—Franchet, Pl. David, i., 124.
H. PUBESCENS, Decaisne, Fl. des Serres, iv., t. 378.—Gardeners' Chronicle, 1884, t. 107

Fig. 3.—*Hydrangea vestita*, var. *pubescens*.—See page 16.

seeds, tubers, bulbs, stems, etc., of all kinds of plants, as well as his specimens for the herbarium and animals and birds. The plants, etc., came to Kew, and many good and interesting things were raised from them.

In the following notes only those plants are noticed which have been distributed or which have flowered and have been noticed publicly in England. Many plants introduced this year are in the collections at Kew and in other botanical gardens and nurseries, but they cannot yet be looked upon as estab-

lished. It will also be noticed that plants which have been introduced a number of years, but have not flowered and been authentically named until this year, are included as new.

Plants not possessed of any value for horticultural purposes are not included, though a few plants of economical importance have been brought into notice during the year. Probably the most valuable of these is the true Sisal Hemp (*Agave rigida*, var. *Sisalana*), which promises to be a source of considerable profit where it can be cultivated on a large scale.

ORCHIDS.—There is a constant, steady influx of new species and varieties of Orchids, but amongst them are only very few of exceptional value in a horticultural sense. The best of the lot is *Vanda Kimballiana*, introduced by Messrs. Low & Co., and flowered for the first time by them in September last. Although allied to *V. Amesiana*, it is, nevertheless, abundantly distinct in foliage and in the form and tints of its flowers. (For a detailed description of this plant see GARDEN AND FOREST, vol. ii., p. 499.) Although not yet flowered in this country, the large quantities of those two reputedly very beautiful species of Madagascar Phaiuses—namely, *P. Humblotii* and *P. Henryi*—which have been imported by Messrs. Sander & Co., must be recorded here as an event of some importance to Orchid-growers. They appear to thrive under cultivation, and are likely to prove better garden Orchids than their delicate, though exceedingly handsome, relative, *P. tuberculosus*. At any rate the two new species are growing remarkably well in a moist hot-house at Kew. *P. pauciflorus*, with white flowers springing from the nodes of an elongated stem, is a recent addition from Java, whilst in *P. Mannii*, which is probably a very fine variety of the old *P. Wallichii*, we have a very ornamental, easily grown Orchid, much superior to all of that section of the genus represented by *P. grandifolius*. It was introduced to Kew from Assam, and flowered for the first time this year. *Grammatophyllum Measuresianum* is a provisional name for a vigorous growing, large flowered species, recently imported by Mr. Sander from the Philippine Islands, and described at length in GARDEN AND FOREST, vol. ii., p. 524. The plants of this genus are not happy, as a rule, under cultivation here, but in this respect *G. Measuresianum* is exceptional, as it grows very freely in a hot, moist house. *Catasetum*, a genus which is now receiving much more attention than formerly, has been strengthened this year by the addition of *C. Darwinianum*, *C. Bungeothii*, var. *aureum*, and *C. galaratum*, var. *pachyglossum*. These are all sufficiently ornamental to appeal to any taste that is not confined to the big and the gaudy. *Lælia autumnalis*, var. *alba*, *L. præstans*, var. *alba*, and *L. anceps amabilis* are all albinos of great beauty. They are the only new additions this year to the *Lælias* and *Cattleyas*, a surprising fact, seeing how numerous the new discoveries in these two genera were until a year or so ago. The only new *Odontoglossum* is *O. Hunnewellianum*, which has bulbs and leaves similar to those of *O. crispum*, whilst the flowers are two inches across, the sepals lemon-yellow, spotted with chocolate, the petals cream-white, spotted with purple and brown, and the incurved fimbriated lip is primrose-yellow, with a blotch of red-brown. It was introduced by Messrs. Sander & Co. from Colombia. *Oncidium Widgreni* and *O. fimbriatum* are botanical additions, as also is *Schomburgkia lepidissima* and *Eulophis bella*. *Cypripedium* has not increased in the number of species, two good varieties of *C. insigne*—namely, *Halleianum* and *Horsmanii*—being the only additions recorded. *Habenaria Macowaniana*, *Satyrium membranaceum* and *S. princeps* are introductions from south Africa, with considerable claims to favor were they not so difficult to manage after the first year. *Disa tripetaloides* is a large flowered, beautiful species, introduced by Mr. O'Brien from south Africa, and which promises to become as valuable in gardens as *D. grandiflora* and the recently introduced *D. racemosa*. *Peristeria Rossiana*, a new Reichenbachian species, with pseudobulbs and leaves like those of *P. pendula*, and flowers like the last named in color and size, but differing in the form of the column and lip. *Zygopetalum lucidum* is a new species imported from British Guiana by Messrs. Sander & Co., and is not very dissimilar from *Z. meleagris*. A few other new introductions of purely botanical interest have been noted, but they are not worth including here. It will be seen, therefore, that on the whole we have added very few good Orchids to those which we possessed last year.

GARDEN HYBRIDS.—If we have exceptionally few additions of any value to record among species and varieties of Orchids, those which have been produced by the breeder and flowered this year for the first time are interesting, and a few are valuable. Probably the finest Hybrid Orchid hitherto obtained in England is *Lælia Digbyana* × *Mossia*, raised by Messrs. Veitch and exhibited in flower before the Royal Horticultural Society, who awarded it a Banksian medal. It combines the most striking characters of its two parents in such a manner as to be very much superior to either. Other hybrids, raised from *Lælia* and *Cattleya*, are: *Cassiope* (from *C. Exoniensis* and *L. pumila*), resembling *L. pumila* in size and color, but not much of an advance (Veitch); *Aurora* (from *L. pumila* and *C. Loddigesii*), a beautiful little hybrid with flowers of good substance, intermediate in size and color between the two parents (Veitch); *Stella* (from *L. crispa* and *C. elegans*), a

decidedly handsome hybrid with the habit of *C. elegans* and the color of the flowers a modification of both parents (Veitch). In *Cypripedium* there have been numerous hybrids and crosses flowered and named during the year. Selecting only the most noteworthy, we have *Niobe*, mentioned last week, a beautiful little plant, as are all the offspring of *C. Fairreanum*; *C. Pitcherianum* (from *C. Harrisianum* and *C. Spicerianum*), described by Reichenbach in January last as “a surprisingly gorgeous flower, not only excellent in color, but also in its uncommon size.” It is dedicated to Mr. Pitcher, of New Jersey, and was flowered in the Sanderian establishment. T. B. Haywood is the only other new hybrid *Cypripedium* of any importance. It was raised in Messrs. Veitch's nursery from *C. superbiens* and *C. Druryi*, and partakes largely of the first named parent. *Cymbidium eberneo-Lowianum* is a hybrid whose parentage is denoted by its name; it was raised by Messrs. Veitch and received a first-class certificate from the Royal Horticultural Society. Several Hybrid *Dendrobiums* and *Masdevallias* have flowered, but they are not worth mentioning here.

Orchard Experiences.—I.

IT is the habit of nearly all branching species of trees, when allowed to develop naturally, to branch from the ground up. When man, for his own ends, counteracts this tendency by the use of the knife, he does it at the expense of growth and of a greater or less detraction from the health of the trees so mutilated. Of course, this truth is not conclusive against pruning, for, in the forest, very straight timber requires the sacrifice of lateral development in the trees, and the requirements of practical convenience in our orchards justify the removal of obstructive growths. And yet we should never quite ignore the fact that even the most scientific maiming of our trees is in some sort a cruelty, which has its inevitable reaction.

The admission by all skilled tree-growers that disbudbing, or penknife pruning, should be the rule, is an acknowledgment of the truth above stated. If we must do harm to the tree for our own future advantage, let us at least do it in the least harmful way. Nothing so quickly destroys a plantation of fruit-trees as the rude pruning with axes which is too often seen in American farmers' orchards, while the scarcely better pruning away of large branches with the saw is working even wider destruction.

It has been my fortune to be an orchardist below the latitude of thirty-eight degrees and on that of forty-five degrees. In the former the evils of rash pruning are far less conspicuous than in the latter, but they are by no means inconspicuous. In the cold north a roughly pruned young tree soon perishes. This fact has led to the hasty advocacy of a let-alone practice; and it is admitted that by it a great deal more fruit will be obtained while the trees are young. But as they grow and their heads become a mass of tangled brush, with the lower limbs and many of the inner ones dying for want of air and light, Nature prunes for us, and, in spite of us, does it more roughly and with more destructive consequences than we should have done it ourselves, however careless or ignorant.

Briefly, then, we are reduced to an alternative choice either to train our trees or let Nature do it, and Nature is very “careless of the single life,” which, in every case, it is our profit to preserve.

The absolute necessity for as nearly iron-clad fruit-trees as possible in the extreme north is demonstrated in nothing more impressively than in our attempt to form an evenly balanced and suitably open head for our orchard-trees. These attempts are sure to fail if the tree is not hardy enough against climate to bear the exposure—not so much to the cold as to the sun's heat and light. A great deal of emphasis is put upon setting the young trees at an angle leaning toward the prevailing winds of the leafy season, and I accept this as good practice everywhere. But as it is in the bare season that the sun's rays work the most damage upon the trunks, the forks and the limbs of our trees, it is not enough.

The prime essential of our northern orchard-practice is to get a sound, sun-resisting trunk; and the varieties which will give us that must be the foundation of our work. We find these chiefly, if not exclusively, among the trees of north-eastern Europe. Upon them we may work our best native iron-clads, not merely standard-high, but upon the limbs. No varieties with a tendency to die in the forks are of any use if we desire a permanent success.

How many main branches shall our trees have? More than two, certainly, for that makes a fork, and experience

inclines me more and more to say not more than three—that is, if you must have your trees of standard height with a bare trunk of four feet and upward, according to their habit of growth.

More and more I am coming to the conviction that in the north the orchard-grower will do better to be his own nurseryman—that is, to grow his own trees from the ground up. He can thus have just such stocks as he wants, and can train and select them from the very start. All through northern New England I have noticed that orchards so grown are the best in every way—in thrift of trees, in selection of varieties and in excellence of fruit.

In the cold north seedling stocks are excluded by the essential condition that not one seedling in a hundred (aside from Siberians, which are short lived) will be hardy and vigorous enough to found a good tree upon. We must, therefore, rely upon root-grafted stocks, and these we will do well to train from the first exclusively by disbudding. A small wound on a nursery tree is comparatively large, and I would avoid it.

With me, so far, Oldenburgh has proved the best variety to set for top-working, which should be done by budding the second season after setting from the nursery, at three years old. But perhaps we shall find an even better stock among the newer importations. Antonorka looks to me promising; Tetofsky has merits as a hastener of tardy bearing varieties. There is still a great deal to be learned in this direction.

Northern Vermont.

T. H. Hoskins.

Celeriac.

THIS vegetable resembles Celery only in the form of its leaf, the edible part being the root, which in full sized specimens is about three inches in diameter. The top, however, if bleached, can be used, but it has not the crispness of Celery and it is stronger in flavor. I plant seeds about the 1st of March in the greenhouse, but they could be set in any sunny window, sowing the seed thickly in a flat, and covering lightly. Paper should be laid over the flat to retain the moisture, and it should only be lifted occasionally to see that the surface of the soil is not drying. The needed water can be supplied without removing the paper, and the plants will usually sprout in two weeks. The paper should then be taken away to prevent the plants from becoming drawn and feeble. They will grow very thickly, and when an inch high should be transplanted into other flats, setting one plant to each two inches square of surface. Here they remain until set in the open ground in the first half of May. I set them in rows two feet apart, with eight inches between the plants. This is not too thick if the plants are not banked, which is not usually done, as for the production of the root, only the earthing up is not needed.

The Apple-shaped Celeriac (Henderson) is the best variety, being smooth and having a small top, the roots all growing from the bottom, and not all about the bulb, as in most other varieties. With clean culture in rich land (and it should be grown in no other) this variety will grow to an edible size as early as September, and can remain out and continue to grow till the hard frosts of the last of October, when it should be lifted and brought into a light cellar where a temperature can be kept at about forty degrees. I set them on the ground close together, watering at first, and when the roots have taken hold they will grow and keep fresh without further trouble. This is an easy crop to raise, and those who fail with the blanching Celeries often succeed with this. The root is not injured by blanching the top after, or even before the root is grown, and this makes both top and root available.

To prepare it for the table, a German friend gives this as the most approved method: Pare or scrape lightly, then boil till tender and slice among cold boiled Potatoes, with mayonnaise dressing; this makes a specially nice and delightful salad. Celeriac is also used in soups, stews and dressings.

Its keeping qualities are good—fully equal to those of Celery. Even after the top is gone, as it will go toward spring, the root remains sound and as good as ever. Those who relish Celery will not go amiss in trying this form of it in the next season's garden.

Clipping Currant Clusters.

SOME experiments were made here last year with Currants by removing the lower half of the flower clusters with a pair of scissors. It is a well known fact that only a few of the berries of any cluster usually mature and the free end of the stem becomes dead before the fruit is ripe. By the re-

moval of this portion before the flowers upon it have opened, it was hoped that there might be a larger and better fruit produced upon the remaining portion of the cluster.

In the experiment alternate bushes in a row were treated with the scissors, and in passing it may be said that this method of thinning can be done rapidly. When the fruit was ripe, the whole product from an average bush, of the clipped and of the unclipped plants, was picked and spread out upon tables. Judges ignorant of what had been done were then called in to inspect the results. No one failed to notice at once the difference and all pronounced in favor of the fruit that had been treated. The berries were larger and of more nearly uniform size and ripeness.

Two hundred berries were next removed from the uncut clusters and it required thirty-five clusters to furnish this number. They weighed, clean of all stems, 152 grams. The same number furnished by thirty clipped clusters weighed 163 grams. These results show that there were about fifteen per cent. more berries to the cluster upon the cut plants than upon the ordinary ones and that these berries were about seven per cent. heavier. The question of quality was only determined by tasting, but there was no doubt in the minds of the judges that the thinned clusters bore fruit of the finest flavor. Like all other fruit currants sell somewhat upon their appearance, and there is no mistake that from the uniform size and ripeness of the fruit, the absence of dead tips on the stems, the clipped clusters were much more attractive.

Further experiments, and upon a larger scale, should be made; but the indications are that there is a point of practical importance in the clipping of the tips of currant clusters at the blooming time.

Byron D. Halsted,

Rutgers College.

Hakea laurina.—Of the many beautiful flowering shrubs belonging to the order *Proteaceæ* coming to us from Australia, this *Hakea* ranks with the very best. A large bush of it when covered with its axillary, ball-like clusters of brilliantly colored flowers, such as is to be met with in the gardens on the Riviera in October and November, is a picture to be remembered. I saw several bushes of it in flower recently, and a box of the flowers just received from a friend residing at Cannes suggests that you in America may like to know something of this shrub. In English gardens it is rarely if ever seen in flower, our climate not being favorable to its setting bloom, although it grows very freely in an ordinary sunny greenhouse. The same circumstance accounts also for the failure here of many other handsome Australian shrubs, which in sunny climes, such as the Riviera, or probably in your southern states, grow and flower profusely. *Hakea* is a genus of nearly one hundred species, all of them Australian. Except *H. laurina* none have beautiful flowers, although many are worthy of cultivation on account of their leaves. In Mr. Hanbury's garden at Mentone I saw recently a bush of this species ten feet high, well furnished with branches. The leaves are alternate, six inches in length, oblanceolate, with prominent parallel nerves and glaucous green in color. The axillary clusters of flowers were very numerous and from their form they are called "crimson sea-urchins." Each cluster is globose, three inches in diameter, and is composed of a great number of tubular flowers arranged closely together, the styles projecting considerably beyond and suggesting the spires of the sea-urchin. The color of the mass of flowers is a glowing crimson, that of the spire-like styles white. It is difficult to convey any idea of the beauty of such a shrub when seen in full flower, but any one who can grow and flower such plants as *Embothrium coccineum*, the *Telopeas* and *Proteas* should secure plants of this *Hakea*. It is also grown under the name of *H. eucalyptoides*.

Senecio macroglossus.—A *Senecio*, with the leaves and climbing habit of common Ivy, and bearing all through the winter numerous elegant flowers as large as Paris Daisies, and colored bright canary-yellow, ought to be a popular garden-plant. But, for some reason or other, it is not. In the succulent house at Kew there are now two fine specimens of this plant, their branches hanging in profusion from the rafters of the roof, and their flowers both abundant and pretty. I have had a few of these flowers standing in water in a room for more than a week, and they are still fresh. There are several climbing species of *Senecio* known in gardens, the commonest, in Continental gardens at least, being *S. mikanioides*, known as German Ivy. The flowers of this plant are, however, no more ornamental than those of Groundsel. *S. macroglossus* was introduced from south Africa to Kew, where it flowered for the first time in 1875. Its leaves so closely resemble those of Ivy that it narrowly escaped being thrown

away after it had been at Kew a year or so, but had not then flowered. The possibility of its proving to be a species of *Hedera*, from Africa, was the means of saving it. Planted in an ordinary border in a greenhouse where it receives plenty of light and air, it soon covers a large space. The branches should be allowed to hang loosely down, so that when in flower the beauty of the plant is properly seen. It goes under the vernacular name of Cape Ivy. H.

Kew.

Water Lilies.—A tank for these aquatics should have a depth of four feet, with a length and width according to convenience, and it may be built in any part of the greenhouse where room can best be spared. Cement is one of the most durable materials for this purpose and at the same time it has a neat

Nymphaea corulea, *N. Devonensis*, *N. alba candidissima*, *N. Zanzibarensis*. *Nelumbium speciosum* is also a handsome aquatic in a heated tank. A good display may be made out-of-doors in summer in a cool tank with the following plants: *Nymphaea odorata*, *Aponogeton distachyon*, *Lymncharis Humboldtii* and *Pontederia crassipes*. These, with the exception of the last, may be planted in tubs or baskets and placed in the tank; the *Pontederia* does not require any soil about the roots, as it floats on the surface of the water. G. B.

South Natick, Mass.

Calanthe Veitchii is a very beautiful species. It is a cross between *Limnates rosea* and *Calanthe vestita*; it is a deciduous plant. The flower spikes vary from two to three

Fig. 4.—Denuded roots of the Bald Cypress, showing knees and underground structure.—See page 21.

appearance. The walls should be eight inches thick, with holes in the bottom large enough to draw off the water when required, and these may be stopped with wooden plugs which should be long enough to stand above the soil. A four-inch pipe around the tank will easily raise the water to a temperature of eighty degrees, the warmth which is necessary, but if the tank is more than twelve feet in width it would be advisable to put in an extra pipe. Good loam to the depth of one foot should be placed in the bottom with a little manure added. To insure an early supply of flowers the bulbs should be planted early in February, putting in enough tepid water to cover the soil and increasing the quantity of water as the plants grow. An essential point in the cultivation of Water Lilies is pure water—*i. e.*, water which has not become stagnant—and this can be secured by inserting a small overflow pipe through the wall of the tank near the top and running in fresh water once or twice a week. The following are a few of the varieties which can be used to make a good display:

feet long, and average from fifteen to thirty flowers on a spike. The flowers are of a rich rose color, with a blotch of white at the base of labellum. *Calanthes* are terrestrial Orchids, and are best grown in pots. The soil we generally use is a mixture of loam, leaf-mold and well decayed cow dung, with a little charcoal and potsherds broken to the size of peas and well mixed in with the soil. These serve to keep the soil porous and fresh. The pots should be well drained and a little moss put over the drainage to keep it open and free from soil. The best time for repotting is just as the plants show signs of making growth. Once in vigorous growth, a little weak liquid manure should be given twice or three times a week. Care must be exercised in using fertilizers in any form, or the foliage may become spotted and disfigured.

This *Calanthe* can be grown in an East India house. It likes abundant light when growing and a fair quantity of sun after the bulbs are formed. This will bring the bulbs to maturity and secure large spikes and perfect flowers.

C. vestita is also a deciduous species of great beauty, and, like *C. Veitchii*, is exceedingly valuable for cutting. It has large, squarish, silvery gray pseudo-bulbs and broadly lanceolate nervose leaves, with tall, gracefully arched scapes of creamy white flowers, with a rich colored spot on the base of the lip. There are often twenty-four and more of these beautiful flowers on a spike. These plants occupy a very small space, and every lover of Orchids should have a few of each kind. There is generally a fine display in our show-house at this season with these flowers, and some Maiden-hair Ferns intermixed with them.

Staatsburgh-on-Hudson, N.Y.

F. Atkins.

Correspondence.

The Knees of the Bald Cypress; A New Theory of Their Function.

To the Editor of GARDEN AND FOREST:

Sir.—From time to time, during and since my first visit to our southern tier of states in 1876, I have examined, sketched and photographed the roots of the Deciduous Cypress—the *Taxodium distichum* of Richard. I was attracted to the tree because of the singular beauty of its form and foliage and by the unusual boldness with which it raises its great, gray, smooth column, sometimes over a hundred feet, perpendicularly, above and upon what an engineer would pronounce a most dangerous foundation—loose submerged sand, the saturated morass or the soft alluvium of low river margins.* But notwithstanding this seeming insecurity, I have never found a healthy Cypress that had fallen before the fierce hurricanes that sweep through the southern forest-lands.†

The surprising and characteristic temerity of the tree is accompanied by another striking peculiarity—it almost invariably, in soft soils, throws upward from the upper surface of its roots conspicuous protuberances that are known as "Cypress knees."‡

These seemingly abnormal growths have attracted much attention, and for more than half a century have furnished an enigma to the solution of which scientific travelers have addressed themselves. Michaux made a careful study of the Cypresses, and in his "Sylva," published in 1819, says: "The roots are charged with protuberances eighteen to twenty-four inches high.‡ These protuberances are always hollow, and smooth on the surface, and are covered with a reddish bark, like the roots, which they resemble in softness of wood. They exhibit no sign of vegetation, and I have never succeeded in obtaining shoots by wounding the surface and covering it with earth. They are peculiar to the Cypress, and begin to appear when it is twenty to twenty-five feet high." Michaux adds, with the frankness natural to a scientific mind, "No cause can be assigned for their existence." Hoopes says in his "Book of Evergreens" (1868): "No apparent function for which the knees are adapted has been ascertained." And Veitch, who seems to have studied the protuberances in England, gives in his "Manual" (1881, p. 216) a picture of a tree growing at Ilesworth, surrounded by scores of knees, and says: "They are peculiar to this Cypress and no cause has been assigned for their existence." That the question continued in this unilluminated condition until recently, was shown in 1882, when I had the privilege of visiting, in company with the highest botanical authorities, Dr. Gray, Thomas

* It is a pleasure to follow Bartram in his enthusiastic burst of admiration for this tree as he writes of it in east Florida 116 years ago: "This Cypress is in the first order of North American trees. Its majestic stature is surprising. On approaching it we are struck with a kind of awe at beholding the stateliness of its trunk, lifting its cumbrous top toward the skies and casting a wide shade on the ground as a dark intervening cloud, which from time to time excludes the rays of the sun. The delicacy of its color and the texture of its leaves exceed everything in vegetation. . . . Prodigious buttresses branch from the trunk on every side, each of which terminates underground in a very large, strong, serpentine root, which strikes off and branches every way just under the surface of the earth, and from these roots grow woody cones, called Cypress knees, four, five and six feet high and from six to eighteen inches and two feet in diameter at the base.

† Elliot ("Bot. of S. C. and Ga.," 1824, p. 643) says: "This Cypress resists the violence of our autumnal gales better than any other of our forest trees." By my friend, Dr. J. S. Newberry, whose extended geological labors have led him to examine many widely separated Cypress-bearing regions in the Mississippi Valley and elsewhere, I am assured that he remembers no instance of the overthrow by the wind of a living *T. distichum*.

‡ Professor Wilson, who has made a careful and valuable study of the species in the forests of southern Florida, and also by cultivation, writes, regarding the formation of these protuberances, "The small roots, which are six or eight inches below the surface, grow upward." . . . "and, upon reaching the surface, turn and go down into the soil." . . . "at each point where the root comes to the surface, begins later the development, on its upper side, of the so-called 'knees'."—*Proc. Acad. Nat. Sci., Philadelphia*, April, 1889. In the organ of the Pennsylvania Forest Association, *Forest Leaves* (December, 1889), is an excellent article by Professor Wilson on the *T. distichum* and a remarkably fine engraving of a tree with enormous knees.

§ I have ridden among them in central Florida in temporarily dry upland basins, where they arose to my breast as I sat upon the saddle, and were not less than seven feet in height above the root.

Meehan, John H. Redfield, John Ball, Professor Carruthers and others, the classic collection of trees planted by William Bartram on the borders of the Schuylkill. There we examined a fine Cypress and the knees it had produced. Dr. Gray then told me that the use to the tree of the knees was unknown. I remarked that they might be a means of raising a point on the root above surrounding water to the end that a leaf-bearing shoot could readily sprout therefrom. To this suggestion he made the same statement made by Michaux and above recorded. Unaware that the subject had been so thoroughly investigated, I have since that period examined hundreds of living "knees" in southern swamps, and found upon them no trace of bud, leaf or sprout, except where some seed may have lodged in a decayed or depressed portion of the surface and there taken root.

In 1887 I had the good fortune to find a number of Cypress-trees under such unusual conditions that their aforesaid subterranean anatomy could be studied without obstruction, and I reached a conclusion respecting the use to the tree of the protuberances, which I have retained in my note-book, awaiting an opportunity to make some further illustrative sketches before placing it before botanists. Some recent publications on the subject, by widely and favorably known authors, have, however, ascribed to the Cypress-knees the sole function of aerating the sap of the parent tree, and this idea bids fair to become embedded in botanical literature. Therefore this communication comes to you earlier than I had purposed sending it.

Stretches of the shore of Lake Monroe, in central Florida, are closely set with large Cypress-trees. They grow in various kinds of bottom—clay, mud and sand. Those of which I shall here speak stood in sand so loose that when the level of the water was lowered the waves readily washed it away and carried it into the depths of the lake. Some four vertical feet of the root-system was thus finely exposed. After several days spent in examining a score or more large trees that had been thus denuded I became convinced that the most important function of the Cypress knee is to stiffen and strengthen the root, in order that a great tree may anchor itself safely in a yielding material.

The word "anchor" is indeed an apt one here, for the living root, curved to its work and firmly grasping the sandy bottom, suggests vividly the best bower-anchor that a man-of-war may throw into similar loose sands, when threatened by the very atmospheric forces that the *Taxodium* has been fitting itself to resist since Tertiary times.*

Truly a most admirable and economical arrangement to stiffen and strengthen the connection between the shank of the anchor and its fluke is this knee, and usually in the living anchor the fluke branches or broadens as it descends, so that its effectiveness is greatly increased, like the sailor's anchor of many flukes, or the "mushroom anchor" that he may have learned to depend upon where the bottom is softest.

The accompanying picture (see p. 20) is from a photograph that I made in 1887 of the lower portion of a tree that rises some seventy feet above the shore line of Lake Monroe. The original surface of the sand was near the level of the higher roots. The picture shows the manner in which this peculiar species throws out horizontal roots from its conical (usually hollow) buttressed base. At different distances from this conical base these horizontal roots project strong branches more or less perpendicularly into the earth. Where such perpendicular "flukes" branch from the main horizontal "shank," it will be seen, there is formed a large knob, which is the "knee" under discussion. This knee, when fully developed, is generally hollow,‡ comparatively soft, gnarled, and very difficult to rupture, so that it has the quality of a spring that becomes more rigid as it is extended or compressed out of its normal shape. When in a hurricane the great tree rocks back and forth on its base, and with its immense leverage pulls upon this odd shaped wooden anchor, instead of straightening out in the soft material, as an ordinary root might; thus allowing the tree to lean over and add its weight to the destructive force of the storm, it grips the sand as the bower-anchor would do, and resists every motion. The elasticity at the point of junction allows one after another of the perpendicular flukes attached to the same shank to come into effective action, so that before

* Professor Shaler, in a most interesting treatise on the nature and associations of *T. distichum*, shows that the Cypress which existed in the Miocene age has since then probably gradually changed its habitat from the drier ground to the swamp areas. See *Mem. Mus. Comp. Zoology, Harvard Univ.*, Vol. XVI., No. 1.

† My friend Thomas Meehan informs me (December 17th, 1889) that he has "observed a case where the interior hollow makes an annual layer of bark equally with the exterior" and he is of the opinion that "it is by the decay of the outer layer of this inside course of bark after several years that the knob becomes hollow." If this habit is general it is an admirable means of forming and of preserving undecayed, at the smallest cost to the tree, a living elastic strengthener at the forking of the roots.

being drawn from the sand or ruptured the combined flukes present an enormous resistance.

The above drawing I have made for the purpose of simplifying the discussion. It shows a hypothetical Cypress with two roots of the same length and diameter—one with knees, the other without them. The superior strength of the stiffened root would seem sufficiently evident; but, with the view of obtaining the judgment of a mind thoroughly trained in questions of this nature, I submitted the drawing to my friend, Charles Macdonald, late Director of the American Society of Civil Engineers, whose eye has been accustomed to estimating the value of strains in structures by an active experience of twenty-five years, and who has just finished the largest drawbridge in America, at New London. Mr. Macdonald agreed with me that the root B, which is trussed with the knees C and C', would very largely exceed in capacity for holding the tree firmly in yielding material the root A, which is similar but destitute of knees. This greatly increased security against destruction by storms is, I think, a sufficient advantage to account for the existence and maintenance of an organ that draws so slightly upon the vitality of the plant.

It is proper to record here another observation that may explain the existence of the elevated, narrow point which the knee sometimes develops and which rises higher than the curved growth that would be necessary to secure the maximum resistance to compression and extension. The home of the Cypress is in broad, level river-margins subject to periodic overflow, where hundreds of square miles become covered with a shallow bed of slowly moving water, or in basin-like depressions, sometimes of vast extent, where from time to time water rises above the level of the horizontal roots. Then these stake-like protuberances, rising into and through the current formed by the drainage or by the winds, catch and hold around the roots of the parent trees many thousand pounds of "plant food" in the form of reeds and grass, or small twigs among which dead leaves become entangled. The tree that exclusively possesses this source of nutrition is at an advantage over all others in the neighborhood, and the higher these attenuated "drift-catchers" rise in the stream, the more drift will they arrest, for the highest stratum of water is richest in float. The theory that some distinguished writers have suggested that the knee is a factor in the aëration of the sap and that the tree's death is prevented by such aëration taking place in the upper portion of the knee during periods of high water, would seem to need careful experimental confirmation. Where nature forms an organ whose purpose is to preserve the life of the individual, she takes special care to adapt such organ to the function it is depended upon to perform. In this case the rough, dry bark of the knee offers a most imperfect means of access for the oxygen or other gases of the atmosphere to the interior vessels of the plant, and instead of presenting broad surfaces of permeable membrane, formed for transmitting elastic fluids, at its upper extremity the protuberance becomes more narrow and presents less surface as it rises, so that when during periods of high water the life of the tree is most jeopardized, the life-saving organ attains its minimum capacity. In the presence of this manifest want of adaptation it also seems important for the acceptance of the aërating theory that some one should experimentally show that the aërating organ of the Cypress really aërates

to an extent sufficient to make it of material advantage to the plant.*

It was long ago observed that no knees are developed when the tree grows in upland upon a firm bottom, in which ordinary simple roots can obtain in the ordinary way the hold necessary to resist overturning forces, and where there is no stratum of water to transport food. So conservative is nature, that she reverts to an original or adopts a simpler form of root even in a single generation if the need for the more complicated arrangement ceases to exist.

Finally, I may perhaps be permitted to add an observation regarding the roots of other trees that trench upon the same soils affected by the Cypress and often take advantage of the anchors it sets so boldly in treacherous bottoms. These trees project their cable-like, flexible roots in every direction horizontally, interlacing continually until a fabric is woven on the surface of the soft earth like the tangled web of a gigantic basket. Out of this close wicker-work, firmly attached to it, and dependent for their support upon its integrity, rise the tree trunks. Thus slowly, and by a community of growth and action, a structure is formed that supplies for each tree a means of resisting the storms. Such communities of trees, provided with ordinary roots, advance against and overcome enemies where singly they would perish in the conflict. The cyclone, the loose sand, the morass—these are the enemies they contend with, as it were, in unbroken phalanx, shoulder to shoulder, their shields locked, their spears bristling against the foe; but the graceful plumed Cypress, the knight-errant of the sylvan host, bearing with him his trusty anchor—the emblem of Hope—goes forth alone and defiant, afar from his fellows, scorning the methods of his vassals, and planting himself boldly amid a waste of waters, where no other tree dare venture, stands, age after age, erect, isolated, but ever ready to do battle with the elements. Twenty centuries of driving rain and snow and fierce hurricane beat upon his towering form, and yet he stands there, the stern, gray and solitary sentinel of the morass, clinging to the quaking earth with the grasp of Hercules, to whom men were building temples when his wardenship began.

New York, Jan. 2d.

Robert H. Lamborn.

A Chart of Standard Colors.

To the Editor of GARDEN AND FOREST:

Sir.—Having read Mr. Orcutt's plea (vol. ii., p. 622) for a "complete nomenclature of colors for field use," permit me to give a few of the reasons why such a work is probably impracticable—reasons which have been made clear to me through practical experience, including the publication of a work intended to supply this well-known want and subsequent experiments on a very extensive scale. A work that would "show every color in nature" would, of course, include a much greater number of hues than are given in my "Nomenclature of Colors" (186), and consequently must be more expensive; yet apparently the chief objection to my book is that it is expensive—the cost is \$4.00. In fact, the expense of publishing such a work lies almost wholly in reproducing the colors, the question of accompanying text being, relatively, hardly worth considering. Mr. Orcutt is mistaken, however, when he says that in my book "only those shades which occur in our native birds are shown," for possibly half of the 186 colors cannot be found in any North American bird, while probably there are extremely few seen in flowers which are not to be found among them.

There are only two known methods by which colors can be represented in book or chart form—by chromo-lithography and by hand-painting. The former is wholly inadequate for the reason that it is limited to a comparatively small number of hues, from which must be omitted nearly all the pure colors and delicate tints. The second, while more expensive, is adequate and practicable, the principal difficulty being to secure absolute uniformity in different copies and editions, and this is a prime requisite, since any variation in this respect would render such a work worse than useless.

I have before me at this moment, as the result of my experiments, a collection of 411 more or less different colors,

*The "Chemical Theory" of the Cypress knee seems to be but a revival of the elaborate hypothesis of Dickinson and Brown, published in their memoir on *T. distichum* in the *American Journal of Science and Arts*, in January, 1848. These industrious observers discard the "Mechanical Theory" entirely, and consider both the spongy knees and, strangely enough, even the spreading base of the tree, as organs of communication with the air, forgetful that the successful and most celebrated lighthouse in the world—the Eddystone—was avowedly modeled after a similar spreading tree-base for the purpose of withstanding the storm shocks of the English Channel. By means of a curious drawing they show how the swollen portions of the base rise "to the top of the highest water level, which must, in some instances, attain an elevation of at least twenty-five feet;" thus continuing the functions and the structure of the knees, "up the body of the tree to the atmosphere."

hues and tints,* no less than 329 of which are made from five pigments. These include all variations of color that it is possible to represent pictorially, and I have devised a method by which absolute uniformity in different copies of each can be guaranteed. The collection is accompanied by clear and simple formulæ for reproducing each, and I can safely say that every objection which has been found to my first attempt in this line (the before-mentioned "Nomenclature of Colors"), except that of cost, has been completely overcome. But this simple question of cost of publication is the problem which I have been unable to solve, and if Mr. Orcutt or any one else can explain how it can be solved, the great desideratum of a complete, simple and wholly satisfactory nomenclature of colors for naturalists of every class can easily be supplied.

Washington, D. C.

Robert Ridgway.

Magnolia glauca in Massachusetts.

To the Editor of GARDEN AND FOREST:

Sir.—In regard to the Massachusetts Station of *Magnolia glauca*, noticed in GARDEN AND FOREST (ii. 612), the following may be of interest to some of your readers:

"The first specimen of the *Magnolia glauca* noticed in Massachusetts was brought from Cape Ann Woods in the summer of 1805, by the late Chief Justice Parsons. He observed a number of the plants in flower as he was journeying on that road, and being struck with their beautiful appearance, gathered a few, which he brought to Boston for examination by his friends. I happened to be at his house on the day he returned from his journey. He showed me his acquisition, and wished to know what it was. I took one of the specimens home for examination, and found it to be *Magnolia glauca*—a most unexpected inhabitant of our region. J. D."

The above is a marginal note, written by Judge John Davis, of Boston, in his copy of the first edition of Bigelow's "Florula Bostoniensis" (a presentation copy to "Judge Davis, from his friend and serv't, the Author") on the page where the *Magnolia* is described.

Needham, Mass.

T. O. Fuller.

The Mild Winter.

To the Editor of GARDEN AND FOREST:

Sir.—On December 28th, 1889, I found *Draba verna* (Whitlow-Grass) in flower and fruit. I have never found this plant in flower in this locality earlier than in the last week in March. On December 30th, I found *Arenaria squarrosa* (Pine Barren Sandwort) in blossom in two places. This plant usually flowers in the first week in June, and though I have often found a few scattering flowers in the late fall, I have never before found it in flower later than the first week in November. I also found on December 30th *Leptophyllum buxifolium* (Sand Myrtle) in bloom. This plant flowers the first or second week in May, and, though it is like *A. squarrosa*, usually a fall bloomer, I have only found it once before in bloom in December.

On January 2d our early spring flowers, *Pyxidanthra barbata*, *Epigæa repens* and *Cassandra calyculata*, showed their buds unusually swollen, but I could find no expanded flowers; but on the same day *Scleranthus annuus* and *Lamium amplexicaule* were in full bloom.

I may add that many grasshoppers are found in the fields, and that, occasionally, moths are seen in the woods. The frogs are croaking vigorously to-day.

John E. Peters.

Pleasantville, N. J., January 2d, 1890.

To the Editor of GARDEN AND FOREST:

Sir.—So mild was the late December that the growth of the various Grasses and White Clover was not checked. On the 31st I gathered *Viola cucullata*, *Taraxacum Dens-leonis*, *Stellaria media* and *Viola rotundifolia*, not scatteringly, but in April-like abundance. A Red Maple (*Acer rubrum*) in the rear of my office is now well covered with blossoms, and has been since the 27th of December. The earliest record of blooming previously is February 7th, 1887. Rose-bushes are putting out a profusion of new leaves. The Japanese Quince is in bloom. Tulips, Hyacinths, Columbines and all the March and April bloomers are up. With growth so started and sap flowing so freely, the results that must surely come with the sudden changes of January and February are not pleasant to think of.

Lawrenceburgh, Ind.

S. H. Collins.

*These may be roughly classified as follows: Grays, 46; browns (including olives), 108; red-browns, brown-reds, etc., 39; yellow-browns, brown-yellows, etc., 31; reds (including pinks), 35; purples, 41; blues, 32; greens, 40; yellows (including oranges), 39.

Periodical Literature.

The *Popular Science Monthly* for January contains an unusual number of articles interesting to students of plant life. One, called "A Harvest from the Ocean," is a description by Professor C. Morton Strahan of Sea-weed gathering on the north-western shores of Europe, and of the uses to which the dried plants are put. Another is a translation from *La Nature* of an essay by Monsieur J. Poisson on "Palm-trees and their Uses." It will, perhaps, surprise the general reader to know that more than a thousand species of Palms, belonging to about one hundred and thirty genera, have now been determined, as against eight or ten species, belonging to half a dozen genera, which were known in the time of Linnæus. The list of uses to which the various parts of very many of these species are put is practically endless, but its extent is at least indicated in M. Poisson's pages. The Date Palm and the Coconut Palm are of course those whose fruit is most widely serviceable to man; but a large number of others furnish food which, either raw or cooked, is useful to savage or semi-civilized tribes. From bridges to dish cloths, from houses to ornaments for the person, there seems to be nothing which, in some part of the world, is not manufactured out of some species of Palm. But the substance least commonly recognized as wrought from a member of the Palm family is doubtless that which we call rattan. It is often supposed to be derived from some sort of cane or bamboo, but is in reality the stem of a climbing Palm or Palm-vine, of which the jungles of the East Indian Archipelago are largely composed, and which sometimes reaches a length of a hundred yards before its continuity is lost to sight in the overarching network of the forest. A striking picture of an avenue of Cabbage Palms in the "Savannah" of Cayenne accompanies this article. Another, likewise translated from *La Nature*, is a superficial chapter on Orchids, which was hardly worth reprinting. And a fourth is a brief but significant word on "The Irrigation of Arid Lands," by Mr. Henry J. Philpott. "There is no more striking difference between the inhabitants of the eastern and western United States," says the author, "than the degree of their familiarity with the word irrigation. And there will never be a profounder difference than will be engendered by the thing itself." Here at the east we irrigate the flower-garden, the lawn, and the vegetable-garden when its contents are first transplanted. "But the idea of watering a whole farm—not a New England 'patch,' but a western ranch of from fifty to fifty thousand acres—seems a financial absurdity. What the eastern farmer could not produce without such expensive cultivation he would say was not worth producing. Equally incredible will seem farming without irrigation to the generation now growing to manhood over a large part of the Pacific Coast. To them it will seem an absurdity not to have the water as fully under your own control as the land. They would not want to cultivate land if they had to take the chances on there being neither too much nor too little rain." Mr. Philpott describes the various methods of irrigation now employed in the west, some of them primitively simple, but others very elaborate, and so costly that the stranger cannot conceive how it pays to employ them merely for pasturage grounds and the raising of hay. In certain soils irrigation continued for some years suffices. The ground becomes saturated and "its former supply may be carried on to reclaim new deserts. . . . Thousands of acres in the San Joaquin Valley have been placed beyond the need of further irrigation. The whole valley was once a desert." Sometimes, indeed, land has been injured by over-watering. "Alkali has been brought on or brought up, the soil has been made heavy, pools have been formed from the 'seepage,' and orchards and vineyards have been spoiled." But how great are the benefits of proper irrigation may be read in the fact that Mr. Philpott speaks of an auction sale of plots belonging to a land and irrigation company where land "which ten years ago was an uninhabitable desert, was knocked down at fifty, a hundred, and even a hundred and fifty dollars an acre. The water rate is extra and is so much per inch used. An inch is the amount that will run through an orifice an inch square in the course of a year." Not the least interesting part of this paper is its reference to the new legal questions which have arisen in a country where the right to the water supply is as important as the title to the land itself, and to the complications which such a state of things has produced in the government's dealings with purchasers. As to the future conduct of the Land Office with regard to water-rights and to the schemes of speculators, Mr. Philpott significantly says, "This is a matter of several hundred times more importance than one eastern man in a dozen will dream of."

Notes.

Twenty tons of Violets are annually used in Cannes and Nice for the making of perfumes and 120 tons of Orange-blossoms.

It is said that as many as one hundred and fifty varieties of preserves are made in Roumania, many of which are flavored with the petals of flowers.

The twenty-third annual meeting of the Minnesota State Horticultural Society will begin at Excelsior, a suburb of Minneapolis, on Lake Minnetonka, on January 21st, and continue four days.

An interesting object exhibited at Christmas-time in the window of a Broadway florist was a piece of a branch of a tree about a yard long and two inches in diameter, from which grew at regular intervals four luxuriant bunches of Mistletoe.

A correspondent writes that it may be true that the use of so many Balsams and Spruces will not endanger the timber supply of Maine, but he adds that he cannot suppress a feeling of regret when he observes among Christmas decorations huge specimens of *Rhododendron maximum*, and entire trees of the American Holly, *Ilex opaca*.

We have received many letters, for which we have no further space, from correspondents who give lists of flowers blooming out of their season. But with Bluets (*Houstonia carulea*) flowering by New England roadsides, *Anemone blanda* opening in the suburban gardens of this city and Dandelions starring the turf everywhere on the day after New Year's, it is safe to pronounce this an exceptional winter.

Croton Alabamensis (see GARDEN AND FOREST, ii., 592, f. 150) is now in flower in the propagating house at the Arnold Arboretum. The bright golden anthers of the male flowers make the inflorescence conspicuous and attractive. The great beauty of this plant consists, however, in the contrast between the brilliant green of the upper surface of the leaves and the snowy white coloring of their under surface and of the young branches.

We have received for examination from Messrs. Johnson & Stokes, of Philadelphia, a label for plants and trees which seems to be a novelty of some promise. It is made of copper, which is durable; it readily receives and firmly retains any inscription, and its tags are so flexible that, with proper adjustment, they need not injure the plant to which they are attached as wire does. We should be gratified to have those of our readers who may be testing this label report the results of their experience.

The increased demand of late years for green for Christmas decoration has caused the introduction of branches of a number of plants into the markets of the northern cities for this purpose. Last week we mentioned finely fruited specimens of the Japanese evergreen Spindle-tree (*Euonymus Japonica*). The supply came from Georgia, and the lustrous foliage makes a handsome contrast with the brilliant scarlet arils of the fruit. The Cassena, too (*Ilex vomitoria*), with its small, shining, evergreen leaves, and clusters of small, bright red fruit, is sold at the north now in large quantities, and is admirably adapted for the purposes of Christmas decoration.

In a late bulletin published by the Ohio Experiment Station, Mr. C. M. Weed gives a partial bibliography and systematic list of the insects which are known to attack Clover. The list includes more than eighty species, and there is little doubt that it will be greatly extended within the next few years, as our knowledge increases. Every part of the plant has its special enemy, from the smallest rootlet to the stem, leaves, blossoms and seed. The ravages of these insects are so serious, especially the destruction wrought by the Midge and the Root Borer, that much apprehension is felt for the future of the Clover-crop, one of the most important of our agricultural products.

Dr. Charles Mohr, of Mobile, sends us specimens of the Nutmeg Hickory (*Hicoria myristicaeforis*) from the banks of the Alabama River, near Hazen, Alabama. This is a new and interesting station for this tree, which formerly was supposed to be confined to the single restricted locality near the coast of South Carolina, which remained, until this Alabama station was discovered, the only place east of the Mississippi River where it was known to grow. Many years after its discovery in Southern California the Nutmeg Hickory was found to be a

common tree in southern Arkansas, and last year it was discovered most unexpectedly in the mountains of north-eastern Mexico by Mr. C. G. Pringle.

A correspondent of the *American Agriculturist* points out some ways in which the grafting of annuals and other herbaceous plants can be made available for special purposes. Cucumbers, for example, may be grown on a high trellis, or around the upper story windows of any building, by training either *Sicyos angulatus* (the Single-seeded Star Cucumber vine), or the *Echinocystis* (Wild Balsam-apple)—either of which will grow to the desired height. Cucumber seed may then be sown in a flower pot, and when the plant is six or eight inches high it may be joined to one of these wild vines at the desired height. Merely scraping the bark of the two plants and tying them firmly together with any soft material is sufficient. They will unite in about ten or twelve days, or sooner, and produce fruits at a height to which the Garden Cucumber could never attain.

One of the largest specimens of Black Walnut probably ever sent to an eastern market in the log may now be seen in the timber yard of Messrs. Johnson Bros., 385 Albany Street, Boston. The tree which produced it grew near the falls of the Kenawah, in West Virginia, on the line of the Chesapeake & Ohio Railroad. The trunk, which measured sixty-four feet to the first branches, has been cut into five lengths; the butt log, the centre of which is hollow from decay, measures at the base eight feet and a half across. The diameter of the log, cut twenty-five feet from the ground, is four feet two inches, and that fifty feet from the ground has a diameter of three feet eleven inches in one direction and three feet in the other. The upper end of the fifth log, at a point sixty-one feet from the ground, where the trunk had been a good deal flattened, measures four feet one inch through one diameter, and two feet nine inches through the other. These measurements are all made inside the bark. A thousand feet of lumber have been cut from the main branches and the five trunk logs are estimated to contain 10,000 feet. The wood in the butt log outside the central cavity is beautifully curled and marked. A superficial examination of the annual layers of growth shows that this great tree has grown on the whole with wonderful rapidity and that it is probably less than 300 years old.

Dr. Hadjime Watanabe, an official of the Japanese Agricultural Service, delivered an interesting address on the Chrysanthemum at the recent celebration in Berlin of the centennial of the plant's introduction into European cultivation. According to the report of his words, published in *Gartenflora*, the Japanese divide Chrysanthemums into two groups—"Nogiku" or wild single, and "Niwigiku" or double cultivated flowers; and the latter are subdivided into four kinds—the ordinary autumn-blooming sorts, the summer-blooming, the winter-blooming, and those which bear flowers at all four seasons. The single flower is not neglected by the horticulturist, but is prized for its very simplicity, and is usually planted at the foot of rocks, intermingled with Grasses, to give a landscape design a naturalistic air. In treating the double-flowered plant when it is desired to produce individual flowers of the largest possible size, then all the branches but one are gradually removed, and on this one only an isolated blossom is allowed to mature. On the other hand, when as many flowers as possible are sought without regard to conspicuous size, the main stem is brought to the greatest possible development, and all its branches are preserved until the blooming season arrives, when, if some show no buds, they are cut away. The sturdiest possible plants are chosen for this purpose and the speaker referred to some upon which more than three hundred flowers had been counted. Two forms are in favor for these many-flowered Kikus, one of which gets its name from its resemblance to a thick broom, while the other is a more artificial, fan-like shape. A Japanese proverb says "it is easy to grow the flowers of the Kiku, but difficult to grow its leaves," and the speaker declared that the plants are judged from this standpoint. The amateur's Chrysanthemums are usually "very poor and faulty in foliage, although they may bear fine flowers; but those which one sees at an 'art-gardener's' are clothed from top to bottom with leaves regularly disposed and of a beautiful fresh color." The most common method of propagating the plant is by root-division, but several others are employed. In one, a single leaf with a bud at its base is plucked, lightly covered with earth and laid in a shady place, where it eventually takes root. Gardeners who own rare varieties therefore forbid the visitor a near approach to their plants, as it would be easy to pick a leaf of the proper kind and conceal it in the pocket for future planting.

The Forests of California.

THE memorial to the congress of the United States which has recently been drawn up by the California State Board of Forestry is most interesting as an official statement of the question which more profoundly affects the material welfare of that state than any other; it is important also because it sets forth with singular clearness of statement the peculiar dangers which beset the mountain forests of that region and the sweeping disasters which must inevitably follow their destruction. The progress and development of many portions of the Pacific states depends almost entirely upon their water supply; so much so that a failure of this supply would paralyze all industry and involve the entire section in bankruptcy. Mining, as at present conducted, can only be carried on where water abounds, and many rich mineral regions along that coast are now unproductive during a large portion of the year on account of an inadequate water supply. It is believed that this inadequate supply is partly owing to the diminution in the volume of many of the streams which head along the slopes and on the crests of the Sierra Nevada Mountains and its spurs and that this diminution is directly traceable to the wanton deforestation of these slopes. Many of these mountain lands have passed into private and corporate hands, and this fact multiplies the difficulties of imposing effectual restraints upon the destruction of timber by fire, by the axe and by the flocks of sheep which are pasturing the life out of the forests. Nevertheless there remain among the water sheds of the Sierra Nevada millions of acres of land still owned in fee simple by the United States. These lands are covered with forests to protect the fountains of the streams which furnish the very life-blood to the mining interests of the state, to its agriculture and horticulture, and to its inland commerce by preserving the navigable flow of the Sacramento and San Joachin Rivers. The custody of these lands, a part of the nation's inheritance, most certainly demands wise management, and therefore the forest officers of California address the general government with the full assurance that they have a right to ask for these mountain forests as careful stewardship as that given to the moneys in the public treasury.

Measures have been undertaken by the general government to punish marauders for cutting timber on the public domain, and yet it is held that the value and volume of all the timber and fuel that has been stolen in California for twenty years past are a trifle when compared with the standing timber and the growing young forests which are swept away every year by the combined agencies of fire and of sheep. It is not asked that there should be any abatement of energy in the suppression of the minor evil, but it is urged that the government falls short of its duty when it permits, without remonstrance, the obliteration of its forests by mountain fires and the more complete extinction of their young growth by browsing animals, even though it does spend a great deal of money in the prosecution and occasional conviction of some comparatively petty trespasser. Recognizing the water-storing character of forests and the danger from freshets which their removal will cause, this memorial invites attention to the added peril which will come from the encroachment of the inhospitable climate of the torrid and treeless districts lying to the south and south-east of the state if the great forests of the north-west coast which help to resist the enlargement of this arid region shall be swept away.

In view of all these dangers the Board of Forestry suggests, in the first place, the temporary removal of the Timber-entry Law in California and the absolute withdrawal from sale of all Federal timber-lands in that state until future surveys have determined the areas and boundaries of such tracts as are necessary to insure the integrity of the streams and natural waterways of the state. Again, it is recommended that the timber of such lands when fit to harvest shall be sold, and not the land. For this land the lumberman cares little. He buys so many feet of saw logs to the acre, and he will pay as much for the timber alone as he will for the timber and the land it stands on. Hence in selling the timber alone there is no loss of revenue to the Government, and while the fee of the land remains in the United States such regulations can be imposed for the preservation of the young growth and for the prevention of fires, as will insure the perpetual forest character of the land and secure continuous revenue for the future. It is worth noting that this plan has already been adopted with good results in Canada. The owners of sheep and cattle have so long used and abused the forest-land as a free range that they have come to think they have a special right to pillage the public domain that is denied to people engaged in other pursuits. But since the conviction of a few timber thieves has abated the once thriving industry of lumber-stealing, the same vigorous process would greatly mitigate the theft of pasture and the fires that invariably accompany it. It is also suggested that encouragement should be tendered to those who are willing to plant large tracts of forest on the mountain and foot-hill lands, which are unsuitable for agricultural use, and as a means to this end the establishment of forest experiment stations in the arid districts of Colorado, California, Nevada and Arizona is advised.

Every one who has had an opportunity to observe the forests of California and to note the influences which are working to curtail them on every side will endorse the concluding statement of this memorial:

The present administration, or rather want of administration, of the Federal timber-lands of this coast, is an arraignment of the best intelligence and patriotism of the general government, which a disregard of the enlightened methods of other nations might not alone challenge, but which a due regard to ourselves and posterity does, and which strenuously and exigently calls for reformation and remedial measures that shall check the menace to our immediate and future prosperity.

It is to be hoped that Congress will not bury this rational and patriotic appeal in the pigeon-hole of some committee room, but that they will give it the deliberate attention which the far-reaching importance of the subject de-

mands. It is to be hoped, furthermore, that this paper will be read and pondered by friends of our forest throughout the entire country. Copies of the memorial can be obtained from Mr. William S. Lyon, forester of the commission, whose address is Los Angeles, California, and who invites the co-operation of public-spirited citizens in every part of the Union in urging its consideration upon the Congress now in session.

A prospectus relating to the new scholarships offered under the foundation of the Missouri Botanical Garden has been issued. Applications for these scholarships, which will not exceed six in number, must be in the hands of the director, Professor Trelease, not later than the 1st of March. A preliminary examination will be held on the 4th of that month. If there are more than six applicants for the scholarships, a competitive examination will be held on the 7th and 8th. The preliminary examination will be confined to English grammar, reading, writing, spelling, arithmetic and geography. The competitive examination, only held in case there are more applicants than scholarships, will embrace the history of the United States, English literature, algebra, German, elements of botany and zoology, and such other subjects as may be prescribed. Arrangements are made by which candidates living remote from St. Louis, who may desire to save the expense of a journey to that city, can be examined at their homes by the principal of some approved school. Successful candidates will begin work in the garden the 1st of April. They are to be lodged in comfortable rooms in a dwelling adjoining the garden under the charge of the head-gardener or some other competent person. Board can be obtained at reasonable cost.

It is the intention of the trustees of the school to make, as far as possible, the surroundings of the pupils home-like, although they assume no responsibility for their behavior outside of working hours. The scholarships may be held for six years, and the incumbents will be paid fortnightly at the rate of \$200 a year for the first year, \$250 for the second year and \$300 for the remaining years. During the first year of their scholarship, garden pupils will be expected to work at the practical duties of the garden nine or ten hours daily, according to the season, and to read the notes and articles referring to the subject of their work in one or more good journals. In the second year, in addition to five hours' manual work, they will be given instruction and will be expected to do thorough reading in vegetable-gardening, flower-gardening, simple fruit-culture and orchard-culture. During the third year, in addition to their five hours' manual labor, they are to be instructed in forestry, elemental botany, landscape-gardening and the rudiments of surveying and grading, and will be required to take charge of clipping or indexing some department of the current gardening papers. The fourth year they are to study the botany of weeds, garden vegetables and fruits, with simple book-keeping and the legal forms for leases, deeds, etc. The fifth year they are to be instructed in vegetable physiology, economic entomology, fungi, especially those which cause diseases of cultivated plants; and each pupil, in addition to his five hours of manual labor, will keep a simple set of accounts pertaining to one department of the garden. They will study, during the sixth year, the botany of garden-plants, trees in their winter aspects, and the theory of special gardening connected with some branch of the work they are charged with in the garden.

With such opportunities for practice and study, a young man of ordinary intelligence and industry ought to be well equipped at the end of his six years, and able to command agreeable and remunerative labor. The demand for thoroughly instructed men to serve as managers of public parks and private estates is large already in this country, and steadily increasing. Skillful plant-growers abound, but really good gardeners, in the broad sense of the term, are difficult to find in America and in every other country.

The Forest Pavilion at the French Exhibition.

THE exhibition of the forest department of the French government at Paris last summer was perhaps the most comprehensive and best arranged display of its kind that has ever been made. The Forest Pavilion, which appears in our illustration on page 32, and its contents, were, of course, of the highest significance to visitors interested specially in forests and their products, and there was, perhaps, no one spot in the whole exhibition more frequented by the general public, who found, apparently, much to attract and instruct in the beauty of the building itself and in the variety of its contents. Indeed, so great was the crowd of people who thronged the building from morning till night, that anything like a critical examination of its contents was practically out of the question.

The building,* constructed entirely of logs cut in the forests belonging to the French government, representing all the indigenous trees of France and covered with their bark, was 125 feet long and nearly 120 feet wide. It consisted of one main hall, surrounded on three sides by a broad porch or piazza, with a half-story added at the rear and reached by an interior staircase, which admitted also to a wide gallery surrounding the main hall. The general scheme of the arrangement was due to M. de Gayffier, Director-General of the French forests, and was carried out most intelligently by a young architect, M. Lucien Leblanc.

Around the interior of the main hall trunks of the different species were arranged as columns to support the gallery, and between these were placed, first, a large cross-section of a trunk of the species, and then above this artistically grouped samples of all the principal objects made from the wood—an arrangement which enabled the visitor to see at a glance the wood of any given species and the principal products manufactured from it. The centre of the hall was occupied by working models of saw-mills and various machines used in working wood, and a number of specimens showing the methods of cutting up logs to the best advantage. The gallery surrounding the main hall contained a large number of smaller wood specimens, a large collection of microscopic slides illustrating the structure of the French woods, models of fungi injurious to wood, a most instructive series of specimens showing the results of different injuries to wood, abnormal growths, and the like, with an immense number of the minor products of the forest arranged systematically under the different species, tree-fruits, seeds, etc.

The most interesting part of the exhibition, to the general public at least, was found in the half-story. Here, in two or three small rooms, comfortably arranged with tables and seats, were maps and plans of French forests and immense collections of photographs illustrating French forest scenes in all their varied aspects. These rooms contained two plans in relief of the torrents of Vaudaine and of Riouchanal, and of various torrents in the Hautes-Alpes, and a series of water-colors of various torrents both in the Alps and in the Pyrenees. Three dioramas most artistically arranged in the rear of the half-story exhibited, in a remarkable and instructive way, the effects of mountain torrents and the labor required to restrain them within reasonable bounds. The first represented the torrent of Bourget in the Basses-Alpes, which for years devastated the valley of the Ubaye, but which, thanks to the intelligence and energy of the French forest-department, is now conquered. This end was accomplished by building a series of dams and by raising the bed of the stream bodily above its natural level, the flow of the water into the channel being checked by reducing the slopes and covering them with a forest of coniferous trees. The diorama shows the break-waters with the workmen engaged in planting the trees that to-day cover 1,200 acres, bordering an ordinary mountain stream which eighteen years before was one of the dangerous torrents of France. The second diorama shows the torrents of Riou Bourdoux, also in the Basses-Alpes, famous for its devastations and the most dangerous torrent of the French Alps. It once destroyed everything along its course and threatened the extermination of Barcelonnette, near which place it has its mouth. The diorama shows a dam constructed by the forest department, a colossal construction in masonry and hydraulic mortar, twenty-five to thirty feet high and nearly 300 feet long, intended to hold back the solid material brought down by the torrent and to prevent the passage of anything but the water. The work was only commenced in 1875, but a young forest already covers and holds the ground which, before it was planted, was entirely bare and

* A description of the Pavilion, with some account of the forest material which it contained, was given in GARDEN AND FOREST (ii, 478, 490.)

subject to constant movement. The third diorama shows the slope of Péguerre near Cauterets. Here it was not a question of restraining a torrent, but of preventing a mountain from sliding down and destroying, in its fall, the town of Cauterets. The work was accomplished by removing, in the first place, all the loose blocks of stone and then by clothing the loose and rocky soil with a vegetable covering consisting of squares of sod held up by cross walls of dry stone. This work, commenced in 1885, has been successfully terminated and the result is considered a marked success. The dioramas were seen through darkened chambers made to represent, in one case, the hut of a forest guardian with its rude furniture, and in another, a camp for the laborers employed on the work represented in the accompanying diorama, the naturalness of the effect being heightened by the presence of their tools and camp equipage.

Some idea of the care with which the Forest Pavilion and its contents were prepared will appear from the fact that the whole building was set up and arranged in the forest of Fontainebleau and then taken to pieces and removed to Paris. It is to find a permanent resting-place in the Bois de Vincennes at the other end of Paris, where it will serve to instruct and delight visitors to the French capital interested in forests and forestry. Indeed, it would be worth preserving for its beauty alone. Far from having the fragile, trivial look of most "rustic" constructions, its excellence in proportion, outline and execution give it genuine architectural character; and this is enhanced by the charm of its color. The panels of wood that cover the wall spaces between the supports are arranged in attractive patterns formed by the contrasting colors of the barks. The design of the piazzas and the interior gallery is particularly pretty, and much skill was shown in giving architectural dignity to the columns which support this last without the use of other material than that elsewhere adopted. Capitals of many curious yet appropriate shapes were made by groups of twisted roots, and were finished below by a simulation of a "cable moulding" formed of bast rope.

There is one criticism to make on this exhibition, and that is the absence of an official catalogue similar to the one published by the French government in connection with its forest exhibition of 1876. Such a catalogue would have added vastly to the benefit which visitors to the forest exhibition of 1889 derived from it.

Down the Rhone.—II.

JUST below Sarraz, but on the eastern shore, lies St. Vallier, where a stone bridge spans the river with two arches that rest on a huge mid-stream pier. Like many Rhone towns, it is a single long row of closely built houses facing the high esplanade formed by the embankment. There could be no more delightful arrangement for the idle stroller or for that still idler fisherman who so perpetually appears in France. What can be caught in the Rhone I do not know, but its banks were lined with placid anglers from Vienne to Avignon—now perched on a lofty water-wall, now cosily nestled among overhanging Willows by some shady pool. Villages abound on the steep slopes—compact little clusters often set on spots where one wonders how they keep their foothold. Now they are surrounded by fields and vineyards, but again they seem carved out of the naked rock that supports them. They must be cold in winter and hot in summer, with no protection from either storm or sun. But to the artist's eye they are faultless, so entire is the harmony between man's work and Nature's. Built of the local stone, they are so like it in color and texture that they seem to have grown as spontaneously as the Poplars in the plain.

Below St. Vallier red disappears from the roof-tiles—only the yellows and dull browns characteristic of the south are seen. Two light suspension bridges sweep into sight, uniting Tain on the east bank with Tournon on the west. The multitude of bridges on the Rhone and the excellence of their construction amaze an American. They are old or new, stone or iron, resting on piers or swung boldly across, but they are always admirable of their kind, and in our practical land would be thought far too costly for the humble towns they serve. Tain lies against the foot of a hill once famous for the vines which supplied the "Hermitage" wine, but now ravaged by the phylloxera. All along the Rhone, indeed, many of the slopes, now so yellow and desolate looking, bore rich vineyards before the coming of the pest. Their beauty, however, has not been hurt so much as their usefulness—there is nothing finer to the eye under this brilliant sun and above these green lowland fields than their naked, glowing yellow.

After Tournon one may speak of mountains on the west bank rather than of hills—the mountains of Ardèche, which

keep close to the river for a long distance, sending out to it long irregular spurs with deep gorges between. The next important town on this side is St. Peray, famous for its sparkling white wine, and across the river is Valence, where Napoleon passed certain youthful years—one may read about them in the delightful if untrustworthy chronicle which Dumas called "*Voyage dans le Midi de la France*." This is the first large town since Vienne, and it is admirably set high up on a hillside crowned by its ancient cathedral. Even from the boat one may look across the plains beneath it and see the jagged peaks of the Drôme country rising against the pallid sky. At every step now the landscape grows more southern in aspect and grander in form; and, did we know history as the traveler should, it would perpetually grow in human interest too. No land is richer in picturesque memories than this land of Provence, which still keeps in its name a record of the first conquest of the Romans in Gaul. It was near Valence that we first saw the Cypress-trees, afterwards ubiquitous in churchyard and burial ground.

At Lavoulte, on the west shore, is an enormous castle, rising high from the centre of the town, with great arcaded walls. No one would guess to look at it that it is now occupied by the employees of a neighboring factory. A great plantation of Cypresses gives a touch of dark color to this splendid mediæval picture, and the hills which follow are covered with a close, yellowish grass dotted with low, dusky shrubs. Poplars and Willows still often fringe the bank where the hills do not come close, and far off a wonderful blue mountain with a scalloped outline seems to bar the course of the stream. Then on the west we see, high up, a stretch of railroad borne by a tall viaduct of pinkish stone, and next a high hill terraced to the water's edge, partly by Nature, partly by man. The usually yellow rock is streaked here with pale gray and black, as one finds it so conspicuously much farther south at Avignon and Vaucluse. In spite of the Cypresses and the Figs and the golden rocks, however, there is a reminiscence of the north in an occasional steep, wooded gorge that has a truly Rhenish character. Looking southward at half-past one we saw the finest of color effects. On all sides were distant mountains of the most genuine blue. To the east was a nearer amphitheatre of hills, some vivid green, some pied green and yellow. The sky was blue and the clouds white, but whiter still was the sun-struck river flowing between pure white beaches fringed with low pale green Willows and filmy little Poplars. Human interest was given by a ruined castle on the western shore, and I thought I had never seen a landscape at once so dignified and so lovely, or one where the beauties of the north and the south were so harmoniously mingled. We had a bright sun tempered by racing clouds all the afternoon, and nothing could be fancied more enchanting than the varying effects they produced, sometimes blending all tones into a low, gentle harmony, sometimes bringing out the local color of tree and rock and tower in the most emphatic way against the azure heaven.

After Le Pouzin, with its feudal ruins, and Baix, a little beyond, with a vast ruined abbey and an eleventh-century church, the whitish towns all straggle along close to the water, and the vast old seigneurial structures rise triumphantly above them, with the hillside as a background. Here are beautiful hills, covered with close vegetation, like a bright green carpet, through which breaks the bluish rock, now in great shoulders and now in long stretches of steeply inclined strata. Sometimes all the western shore shows the blue tone of this rock and all the eastern the vivid green of cultivation. Again the hills are gently rounded, with very wide valleys between, running back at right angles from the stream, scattered with tufts of vegetation that do not conceal the bony structure beneath it, and striped by mountain roads like snowy ribbons.

After Rochemaure, where the basaltic rocks are quite purple, and the village was redder than usual, like many of the slopes, we race under another bridge, and reach Viviers, built on a narrow ledge, with a rock wall rising close and high behind the tall Gothic nave of the cathedral and its octagonal Romanesque tower.

Beyond this the hills are very bare, only sparsely dotted with close grayish shrubs and patches of pale grass. The general effect was all light yellow, broken only by an occasional fringe of green by the river; and frequently the rock had weathered to a sponge-like surface. At Donzère came one of the grandest scenes of the voyage, the river running through a defile between close high mountains. At Bourg St. Andréol, which we reached at half-past three, the hills had broken away to the right and the silhouette of the long street stood out sharply against the sky. First came the great white cathedral, with its semi-circular apse, arcaded octagonal tower and low

stone spire ; then a fine sixteenth-century house, where, over the high court-yard wall, showed a mass of deep green foliage and a huge blazing pink Oleander ; then a beautiful gateway of Rococo iron, and then an inn where the whole façade was hidden up to the second story by three huge specimens of *Euonymus Japonica*, growing in tubs and loaded with creamy blossoms. No plant is more common in southern France than this, and none is more beautiful unless it be the Oleander. We do not know in the least what an Oleander is, seeing it of small size, with sparse foliage and scattered flowers. One must see it where it is at home out-of-doors—often a veritable tree in dimensions and covered so close with blossoms that it looks like a huge bouquet.

It was nearly four when we reached Pont St. Esprit, with its ancient bridge dating from the latter half of the thirteenth century. It is 2,500 feet long and rests on nineteen great round arches and three smaller ones, and but for certain alterations made in iron at one end, looks just as it did 600 years ago.

Passing on, the shores stretched out in broad plains, and to the south-east appeared a lofty mountain, almost as white as snow to the top. Soon a single nearer peak came into view, with a jagged long hill beneath it, every point accentuated by a ruin. Wide amphitheatres of hills succeeded, and then a great long cliff of slanting strata, behind which still rose the far-off snowy mount. A castle of the same yellow as the cliff crowned its summit, and the river swept around its base straight toward the east, and skirted another similar cliff bearing another castle. These are the hills of Mondragon and Mornas, and the white mountain is Mont Ventoux which one still sees from Avignon. Nothing more splendid could be fancied than the color here, or than the bold yet harmonious forms of the hills, as steep and naked as walls in their upper portions and sloping and green below. The winding of the river shows them in ever-varying perspectives and each new point of view we think the very best. A little below come flat lands for a change, but with mighty ranges of mountain beyond them. At St. Etienne-des-Sorts we found a nest of yellow houses with a tall-bodied church bearing a tiny square tower. The naked soil was almost orange-colored here, and we knew we were in the *midi* indeed, seeing our first Olive-trees. At a quarter past five we passed two great towers, one round and one square, frowning at each other from isolated rocks across the stream, and, like the rocks, streaked yellow and gray. Looking back we still saw the great white mass of Mont Ventoux, and looking ahead we gazed now south, now east, now west, as the river wound about a succession of broad islands and under the edges of projecting rocks. It was a mighty stream by this time, having been fed by many tributaries since we started, and broadening out around a succession of large islands, yet seeming to flow more swiftly than ever. If every foot of the way had seemed a new delight, how shall I describe the approach to Avignon? The hills break away into more distant amphitheatres. The stream goes east, then turns south, and over its two arms and the green island between them we see afar off a high rock crowned by a diadem of massive golden towers. At this distance, against a sky already reddening for the sunset, it looked like a vision of the New Jerusalem. As we got nearer it was impossible to seize all the features that made up the splendid landscape. There was Avignon itself, lordly on the left bank, and, almost as lordly, the towers and walls of Villeneuve-les-Avignon on the right. Between them were the two wide arms of the rushing pale green stream, with a large bright green island between them, cut by endless rows of pollard Mulberries. The shores were fringed on the right with Poplar groves, while on the left rose groups of tall, black Cypresses. A great stone bridge crossed the prospect in the distance, and nearer were the remaining arches of that famous ancient bridge where, says the nursery rhyme, all the world has danced. Around all stood yellow peaks topped by picturesque ruins, and, still further back, the exquisite blue lines of mountain. It was all beauty, all grandeur, all romance, condensed into a single picture, and as the boat swept up to the *quai*, the western sky burned with a roseate splendor that was reflected from the water in great flashes and turned the yellow castle walls to pink.

The charm did not fade when we saw the inside of Avignon and the panorama from its towers, and from those of Villeneuve across the Rhone. And when to this was added a visit to Petrarch's Vacluse—so often described, so wholly undescribable—it seemed as though, could one see but one beautiful place on earth, Avignon would be the place to choose. Yet one may stay there weeks and never really see it, for its very best shows only when one comes upon it in a summer sunset by the great water highway.

New York.

M. G. Van Rensselaer.

New or Little Known Plants.

Phalænopsis, F. L. Ames.

IT can be said of very few plants that an individual represents all there is of a particular form or variety or hybrid which, not being reproducible from its own seed, must perish with the individual, and so disappear unless the conditions which produced it happen to produce another individual similar to the first. Such unique plants are always interesting in themselves, and the interest increases from a horticultural point of view when they have qualities which make them valuable for their beauty apart from their rarity. Such a plant is the *Phalænopsis*, of which a figure appears on page 29 of this issue. A few roots and three small leaves are all there is to represent this plant, which is a hybrid raised in England by Mr. Seden, the successful Orchid-hybridizer in the Veitchian Nurseries. It was bred from *P. amabilis*, a plant known in gardens often as *P. grandiflora*, fertilized with the pollen of *P. intermedia*, itself a hybrid between *P. rosea* and *P. Aphrodite*. The seed which resulted from this cross was sown in 1882 ; one plant appeared, and five years later (a wonderfully short time for a seedling Orchid to grow to the flowering state) this plant flowered. It was exhibited at a meeting of the Royal Horticultural Society, and was described by Mr. Rolfe in the *Gardeners' Chronicle* of February 18th, 1888, in which a figure of the flower was published, the hybrid being named for Mr. Frederick L. Ames, of North Easton, Massachusetts, to whose collection it was added in the spring of the same year. It has just flowered for the second time at North Easton, and although the plant is in excellent health, it carries only three leaves and is so small that the immediate prospect of increasing it by division is not good. Four flowers were open at the same time this year on the long stout scape ; they were fully three inches across, with pure white sepals and petals. The lip, almost identical in shape with that of *P. amabilis*, is marked with bright red-purple on a ground of yellow or yellow-white, the crest being yellow striped with purple. As Mr. Rolfe has pointed out, the flower "is remarkably intermediate between its two parents, and makes a decided step backward to the *tendrillea* section of the genus." We are indebted to Mr. Ames for the opportunity of figuring this beautiful and interesting plant.

Foreign Correspondence.

The New Plants of 1889.—II.

STOVE AND GREENHOUSE PLANTS.—The most remarkable plant in this division is the gigantic Aroid, *Amorphophallus Titanum*, which, although introduced to Kew ten years ago, did not flower in Europe until June of this year. A description of this extraordinary plant has already been published in GARDEN AND FOREST. I may observe that the plant at Kew is apparently in good health, and beyond losing eight pounds in weight through flowering, the enormous tuber was not otherwise affected. *A. Eichleri*, a small species from the River Congo, has also flowered this year at Kew. It is an interesting and ornamental plant of its kind, but it emits a horrible stench when in flower. *Arisæma Wrayii*, a new species from Perak, with the habit of *A. nepenthoides* and a spathe six inches long, colored white and emerald green, is a pleasing addition to the cultivated plants of this genus. *Arisæmas* are as easily grown as tuberous Begonias, and the flowers of most of them are exceptionally quaint and attractive. *Carludovica palmifolia* is a provisional name for an elegant leaved plant, certainly a *Carludovica*, which Mr. B. S. Williams has introduced this year. *C. rotundifolia*, a near ally of the well known *C. palmata*, from which Panama hats are made, is another addition to ornamental foliage plants, and it is also attractive in its Medusa-like inflorescence and the rich colors of its fruits. It has been in cultivation at Kew some years, but has only recently been definitely named and figured in the *Botanical Magazine*. Mr. Bull offers under the name of *Encephalartos regalis*, from Zululand, a Cycad which resembles *E. Hildebrandtii*. Kew has distributed this year the only noteworthy Palm, namely, *Catoblastus præmorsus*, from Venezuela, with compact habit

and elegant bright green pinnate leaves, as delicate as those of *Cocos Weddelliana*, and likely to prove as useful. Nepenthes receive more attention now than they ever did, and in addition to the numerous seedlings and hybrids in cultivation, we possess many distinct and beautiful species. To the latter Messrs. Veitch have added *N. Curtisii*, var. *superba*, remarkable for the rich brown-purple blotches on its long, elegant, narrow pitchers; and *N. Burkei*, a Bornean species recently described by Dr. Masters, and which is peculiar in having cylindric pitchers, inflated at the base, and wholly destitute of wings. *Sarracenia decora*, a hybrid with pitchers nine inches long, colored reddish brown and tessellated with white, and *S. Wrigleyana*, a prettily marked hybrid from *S. psittacina* and *S. variolaris*, are two distinct additions to the many side-saddle-flowers which are cultivated in English gardens. *Amomum magnificum* has been already mentioned (vol. iii., p. 8); it is likely to become a useful plant in furnishing large tropical

the beauty and useful character of these two plants. *E. Makoyanum* was introduced in 1885 from Brazil, by Messrs. Makoy & Co., of Belgium. *Solanum pensile* is a lovely climber from Demerara, which festooned the rafters of one of the stoves at Kew this year with long pendent racemes of purple-blue flowers, as fine as those of the *S. Dulcamara*, the Bitter-sweet of our hedgerows. *Tecoma Smithii* is a beautiful flowered hybrid from *T. Capensis* and *T. velutina*, raised in the Melbourne Botanic Gardens, and sent this year to Kew, and to Mr. Bull. It is described as being one of the most beautiful of all the Tecomas, the flowers being large, in enormous panicles, and colored bright orange and chestnut. It will be a useful plant for the greenhouse or conservatory, but like all Tecomas, its flowering depends much on its enjoying plenty of sunlight at all times. *Protea nana* is a charming greenhouse plant, with linear Heath-like foliage and nodding terminal cup-shaped flowers, like magnificent *Genethyllus tulipifera*, and colored

Fig. 5.—*Phalenopsis* F. L. Ames.—See page 28.

houses. *Dracena marmorata* is a large species in the way of *D. Lindenii*, but with curiously mottled leaves. It has been introduced from Singapore to Kew and flowered and named this year. *Allamanda violacea* is not new to cultivation, but it had been lost sight of for many years until this year, when plants of it flowered at Kew. The best colored variety of this very interesting species is a first-rate stove flowering plant. *Echites atropurpurea* is another tropical Dog-bane which was in cultivation at the beginning of the present century, and then disappeared again until this year, when it flowered in a garden at Croydon and was sent to Kew as a new plant. It is a free-growing climber, small leaved, with numerous racemes of dark purple flowers, similar in shape to those of *Dipladenia Boliviana*. *Epiphyllum Makoyanum*, a variety of what was introduced in 1885 as *E. Russellianum*, var. *Gaertneri*, but which is almost certainly a third species of the genus, was certificated this year as a new plant. Whatever the decision in regard to names may be, there can be but one opinion as to

rich blood crimson. The Proteas are worthy plants for the greenhouse, and especially for countries where the climatic conditions resemble those of the Cape, where these plants abound. This species and *P. longiflora*, with oblong leaves and erect, large white flowers, have been introduced and flowered this year for the first time at Kew. Another Cape plant, but of a very different nature from the Proteas, is *Drosera cistiflora*, whose flowers were first developed this year at Kew, and were the delight of both botanists and gardeners. A Sundew, with linear leaves on an erect stem, five inches high, and terminated by a poppy-scarlet flower, cup-like and two inches across, could not fail to cause some excitement amongst those who were familiar with the comparatively very small flowers of the common Sundews. It is satisfactory to be able to state that the plant at Kew is growing freely, and promises to be as easy to cultivate as *D. Capensis* and other Cape species. Another Cape Sundew, of much greater botanical interest even than the Cistus-flowered *Drosera*, is *Roridula*

dentata, large plants of which are in the Edinburgh Botanic Gardens. It is a shrub, with hard, woody stems and long linear leaves clothed with viscid glandular hairs, as in *Drosera*; and it bears terminal racemes of white flowers. A shrubby Sundew, attaining a height of three or more feet, and with leaves so sticky as to render the plant, when hung up in the house, useful at the Cape as a fly-catcher, is a novelty of no ordinary kind. Seedlings of it are in the Kew collection. Still another new plant from south Africa is *Gerbera Jamesoni*, which has already proved a charming pot-plant for the greenhouse, and may also prove hardy in the neighborhood of London. It has pinnatifid hairy leaves about a foot long, and single-flowered scapes, the flowers or heads four inches across, not unlike the Paris Daisy in form, and colored bright flame-red. This is certainly one of the best of the new introductions of this year. *Olearia insignis* is a very striking addition to the goodly number of the *Olearias* already in cultivation in England. It flowered for the first time last year at Kew, but I do not remember that it has been recorded amongst garden plants. It has numerous elliptic or oblong leaves, nine inches in length, and the whole plant is thickly felted with white wool. The flowers are on axillary peduncles, and are in the form of the common Scabious, two inches across, orange-colored in the centre, the ray-florets white. It was introduced from New Zealand, and is figured in *Botanical Magazine*, t. 7, 034. *Chironia peduncularis*, the handsomest of the genus, forming a compact shrub, two feet high, with heart-shaped shining green foliage and terminal panicles of erect, Gentian-like, star-shaped flowers, one and a half inches across, and colored rosy purple, is a useful addition to easily grown, free flowering greenhouse plants; *C. palustris*, smaller in all its parts, and fleshier, but a pretty and very floriferous plant, is almost as good. Both these species have lately been introduced from the Cape, and they were this year much admired at Kew. The first named is figured in *Botanical Magazine*, t. 7, 047.

Amongst hybrids raised in English gardens there are, of course, many plants of first-class merit. Messrs. Veitch continue to add beautiful, free flowering Rhododendrons raised from Malayan and Javanese species. It is impossible to speak too highly of this race of plants, which are certain to fill a very large place in all well furnished greenhouses. Streptocarpus, too, is proving a good, useful genus, the various hybrids and crosses recently raised at Kew from *S. Dunnii*, *S. Rexii*, *S. lutea* and several other species clearly proving that a race of plants as useful in the greenhouse as Gloxinias are in the stove may be expected from them. M. Lemoine's new race of Begonias, obtained from *B. Socotrana* and some other species, probably *B. semperflorens*, may be expected to take a favored place among the stove Begonias when once their cultivation, at present a failure in some gardens, is understood.

BULBOUS PLANTS.—Whilst those races of bulbous plants such as the Hippeastrums, Nerines, Liliums and Narcissi have continued to improve in the hands of the breeder of new kinds, there are very few new introductions of any bulbous plants whatsoever to record this year. The only stove bulb is *Crinum Brachynema*, which, although introduced from Bombay and flowered at Kew in 1870, does not appear to have become established in gardens. It has lately been reintroduced in quantity, and flowers of it were sent to Kew for name a few months ago. It has large umbels of pure white, substantial flowers with long tubes, a limb three inches across and fragrant as Cowslips. It is likely to become a rival to *Eucharis* should it prove amenable to ordinary cultivation. *Nerine angustifolia* is remarkable for its very long flower-scapes, some of the plants at Kew this year producing scapes three feet long, and bearing an umbel of about twenty rosy red flowers, similar to those of *N. flexuosa*. *Tigridia Pringlei* is likely to become, a favorite here, though it is very similar to *T. Pavonia* both in form and color. *Gladiolus Leichtlini*, a new introduction from the Transvaal, with bright red flowers like those of *G. psittacinus*, and *G. Adlami*, from the same region, with flowers dull yellow spotted with red, otherwise similar to *G. cardinalis*; these two new species have been flowered at Cambridge. The hybrids *G. turcensis* and *G. Nanceianus* are both very beautiful breaks of continental origin, being large in flower, distinct in shape and beautiful in colors. They are the progeny of *G. Saundersii* and *G. Gandavensis*, and are perfectly hardy in England. Messrs. Veitch & Sons exhibited a collection of the Nanceianus race before the Royal Horticultural Society this year, and they were generally admired. *Watsonia iridifolia*, var. *O'Brieni*, is a pure white flowered variety of a robust, free flowering, easily grown plant, and is likely to become popular. It is the plant which Mr. Goldring mentioned as *W. iridifolia*, var. *alba*. It was in-

troduced from south Africa by Mr. O'Brien, of Harrow. *Lilium Wallichianum*, var. *superbum*, is a noble Lily from India, introduced and flowered this year by Messrs. Low & Co. It has a stout stem, six feet high, bearing three or four flowers, each nine inches long and six inches across the limb, the color milk-white with a pale yellow throat. The Indian Liliums are difficult to establish in English gardens, otherwise they are first-class. We have now *L. Nepalense* (introduced last year), *L. Neilgherrense*, *L. Philippinense* and *L. Wallichianum*, but they gradually weaken under cultivation. A new variety of *L. longiflorum* from Hong-Kong and the newly discovered *L. Henryi* from China are in cultivation at Kew, but they have not yet flowered. *Fritillaria Bucharica*, from central Asia, is an interesting species with whitish flowers borne singly in the leaf-axils near the top of the stem. *Galanthus Fosteri*, from the province of Sirwas, in Asia Minor, has flowers like the larger forms of *G. Elwesii*, and leaves as broad as in *G. latifolius*. Although not new plants, it may be worth recording of *Anomatheca grandiflora*, *Anoganthus brevifolius* and *Cyrtanthus luteus*, three south African plants which have not yet got far beyond botanic gardens, have proved exceptionally easy to manage, very free flowering, and sufficiently ornamental to take a place among small bulbous plants for the cold house or frame.

HARDY HERBACEOUS AND ALPINE PLANTS.—The best of the new plants in this department are several Irises, notably *I. Gatesii*, from Turkestan, related to *I. Susiana*, but larger and better in color even than that superb plant; *I. Barnumæ*, an Armenian species of the *Oncocyclus* section, but with large purple flowers like the German Iris, and *I. Bakeriana*, also from Armenia, with the habit and appearance of *I. reticulata*, the flowers purple and yellow, fragrant as violets, and appearing in February or even earlier. *Spiraea Kamtschatika*, recently introduced and named *S. gigantea*, a plant like our Meadowsweet, but much larger, attaining sometimes a height of ten feet, the enormous panicles of white, feathery flowers, very fragrant, is likely to prove valuable for bogs and swamps. It was exhibited recently by Mr. G. Paul. *Primula petiolaris* and *P. Poissoni* are small though pretty additions to this already largely cultivated genus. *Primulina Tabacum*, an interesting Gesneriad from China, is one of Dr. Henry's discoveries which flowered at Kew this year. It has a tuft of obtuse, lobed, leathery leaves and erect viscid scapes of Phlox-like flowers, one inch in diameter, violet colored and exhaling an odor of tobacco. *Podophyllum pleianthum* is another Chinese plant which Dr. Hance described as one of the most interesting discoveries he ever made. It flowered at Kew this year. The leaves are peltate lobed, a foot across and shining green, while the flowers are not unlike those of the Snake's-head and colored deep crimson. *Clintonia Andrewsiana* is a Californian Liliad of some interest with terminal umbels of rose-red flowers not unlike some of the *Aliliums*. *Calandrinia oppositifolia* is a Californian perennial which this year was very attractive out-of-doors at Kew; it bears white, star-like flowers two inches across. *Kniphofia Natalensis* is a slender species with pleasing, orange yellow flowers, not so attractive as the popular garden kinds, but still an interesting plant and of some ornament.

TREES AND SHRUBS.—The only noteworthy introductions amongst these are *Rosa gigantea*, a magnificent species from the high regions of upper Burmah, and likely to prove hardy at Kew. It has enormous, cup-shaped flowers, six inches across and snow white. *Cornus Sibirica*, var. *Spathii*, is a variegated leaved form of a useful garden shrub, and *Skimmia Foremani* is useful either for out-of-doors or as a pot plant for in-door decoration in winter.

Entomological.

A New Elm Insect.

(*Zeuzera pyrina*.)

SCARCELY a year passes nowadays that does not bring to light some insect newly imported from a foreign country. These importations are in no case desirable acquisitions, and, as a rule, become our most destructive pests. The Elm has suffered for some time from the attacks of the imported Elm-leaf beetle (*Galeruca xanthomalana*), and now it seems settled that another pest has gained a foothold among us, and threatens destruction to our Elms by boring into the branches.

This species is the *Zeuzera pyrina*, Fabr., in the imago stage a very handsome white moth, rather closely spotted with black, as shown in the figures.

For several years back single specimens of the species have

been found in the city of Newark, and their occurrence has been deemed accidental, owing to the small number; but they increased steadily, and for the three years last past they have been numerous around the electric lights along Broad Street, especially near the parks containing many Elms. This occurrence pointed to the Elm as their probable food-plant, and some

Fig. 6.—*Zeuzera pyrina*.

a, Male moth; b, Female moth; c, Caterpillar, dorsal view; d, Caterpillar, lateral view.

of the Newark collectors tried to find the early stages, but sought them in the trunk and roots without success. Finally Mr. Angelmann, examining the branches of a felled tree, found the larva of the borer in considerable numbers in the smaller twigs, and in burrows in larger branches found also the pupa. The moth, it seems, deposits its eggs in the fork of a small branch, and the young larva burrows downward toward the larger branches, tunneling generally through the centre, and usually killing the branch. In color the larva is whitish, as is usual with borers, with black dots, each bearing a single hair, arranged as shown in the figure, which also gives very well the general appearance of the caterpillar. I understand that the terminal branches of many of the trees in Newark have been noticed to be dying, but the cause has not been heretofore discovered. There is little doubt that this insect is responsible for the injury, and that it has gained a firm foothold. That it is spreading is indicated by the fact that during the season of 1889 it made its appearance at Arlington, a suburb of Newark. The insects are attracted by light, and many hundreds of them are drawn to the electric lights and destroyed; these are mostly males, however. There is no reasonable doubt that this destruction of the moths has done much to prevent a more rapid spread, and it is to be feared that once out of the influence of the electric lights their march will be rapid.

As to remedies, I have no suggestions to make at present. Borers are hard to deal with at best, and a borer that attacks branches from sixty to seventy-five feet above ground is an especially unsatisfactory creature to deal with. Heroic remedies would be best here, and I would recommend free cutting and burning of affected branches as the best means of checking their increase and spread.

Rose Notes.

THE closest attention is needed in the Rose-houses during midwinter to ensure success, and all extremes should be avoided, not only in moisture, but in heat and ventilation; in fact, but little of the latter will be necessary until the sun gains power and the days are perceptibly lengthened.

In many instances the crop will have been cut to a greater or less extent during the holiday season, and the next care on the mind of the grower is to make his Roses break well again for the following crop. With this in view, a little extra stimulation in the form of liquid manure may be given, or else a light sprinkling of hen manure may be applied to the surface of the beds. The latter should, however, be used with caution, as its action is somewhat similar to that of guano.

In the matter of watering, much judgment must be used, as an open, porous soil will allow of much more water without injury to the plants than can be safely given to those planted in heavy, clayey soil, which are, upon the whole, rather difficult to keep in the proper condition during bad weather. In either case it will be found that some portions of the beds will dry out much faster than others, and therefore will need much more frequent waterings. During the sharper weather to be expected in January, the firing will naturally be more brisk, and there is in most greenhouses an extra warm and dry corner, especially in those where the boiler is built into the end of the house, and it is in just such places that red spiders are likely to flourish if undisturbed.

To avoid the spread of these pests, special care should be given in syringing these dry corners, so that the spider cannot secure a foothold.

Malformed and knotty buds are frequently seen on some varieties at this season, and they should be cut off as soon as discovered, since it is a waste of the energies of the plant to allow it to finish the growth of such a bud, apart from the valuable time lost by the grower while waiting for the development of a flower finally decided to be worthless.

Good Roses have been rather scarce during the past holiday season, the mild weather of December having disarranged the calculations of many growers. In addition to the high temperature, most of the month was very damp, both of which conditions were far from beneficial to the Rose-crop. In fact it has been anything but an ideal season for Rose-growing thus far, and this serves to impress upon the minds of growers the truth that although a Rose may be an every-day kind of plant, yet it is not an every-day occurrence to see a house of Roses in perfect condition.

The early crops of Hybrid Perpetuals have not been up to standard in many cases, though some good houses are to be seen, while others have proved total failures. This latter condition was not a surprising one on account of the excessive rains of the past summer, the frequent downpour rendering it almost impossible to properly ripen the wood for early crops. Among the earlier hybrids Mrs. John Laing and Madame Gabriel Luizet take a prominent place, these being among the most beautiful of pink Roses, and both are readily forced.

Each of these two excellent varieties has many admirers, Madame Luizet being, perhaps, the largest flower, though Mrs. Laing possesses some advantage in point of form.

It is said that Wootton is producing the best result in the hands of the introducer. Possibly the needs of this variety are better understood there than elsewhere.

Another addition to the list of Roses is now offered by a western firm in the form of a sport from Papa Gontier. From the description, this new candidate for public favor seems to be of questionable merit, the novel feature being its variegated color, which is more or less splashed with different shades. It does not appear that this would be an improvement on the type.

Holmesburg, Pa.

W. H. Taplin.

Christmas Roses.

SINCE the notes on these plants published in GARDEN AND FOREST of January 1st were written, other species and varieties of Hellebores have come into bloom, namely: *H. orientalis*, *H. abchasicus*, *H. niger*, *H. niger angustifolius*, the variety known as the Scotch, or Wardie Lodge form, and *H. niger maximus*. They make a very interesting group, thanks to the abnormal mildness of the season, and they were equally good last year. The winter of 1888-9 and the present one, so far, have been distinctly English, and our Hellebores have flowered above the snow (when there has been any), actually

and not "traditionally," as seems to be the case with Mr. Gerard's plants. I have grown Hellebores both in England and Ireland, and the growth made by plants here equals in every way that made in the British Islands, and there is no reason to doubt that if Hellebores are so planted that they may be covered with a cold frame in the event of cold weather, these beautiful flowers may be had in perfection in America, even in severe seasons, as frost has no injurious effect on the flower buds, and the sunshine of bright days would be sufficient to fully expand the flowers. As to exposure to the sun in summer, it must be taken into consideration that M. Correvo's cultural directions, when applied to this country, should be adopted with some modifications. We have found that in light soil, during protracted dry weather, the large, leathery leaves become veritable signals of distress unless water be applied; hence the advisability of planting in

known as it should be, taking into consideration the fact that no other flowers are to be had out-of-doors, even in a mild season like the present.

Passaic, N. J.

E. O. Orpet.

Propagating Chrysanthemums.

IN the last issue of GARDEN AND FOREST a Japanese authority is quoted as saying that Chrysanthemums are sometimes propagated in his country from a single leaf with the bud at its base. Permit me to add that at the November Chrysanthemum Conference, in London, Mr. R. Beale exhibited some small Chrysanthemum plants, said to have been grown from leaves only, and they were naturally objects of considerable interest. In a note to the *Gardeners' Magazine*, in the same month, Mr. Beale explains that these plants were not strictly obtained from the leaves only, but that the axillary bud was

The Forest Pavilion at the French Exhibition.—See page 26.

soil of a retentive nature, when the preference is to be had. An examination of the roots of Hellebores will show that the young growing parts are covered with minute root-hairs or feeders, and these must, of necessity, suffer severely in the event of drought. As to the proper time for division, while it may be possible to divide the plants after the foliage is matured in June, we would not risk advising any one to perform the operation at this season, unless he had time to nurse his plants afterward, while it may be done safely and easily in early spring before growth commences, or in September, when strong sunshine is past. It is rather difficult to understand how a "warm cold frame" differs from "a cold house from which frost is excluded," as in either case the plants must be lifted again in spring. The placing a cold frame over Hellebores in their permanent quarters would hardly chill the enthusiasm of any lover of flowers. Recent visitors here have expressed surprise that these plants could be grown in eastern gardens, and there is no doubt that this is not so generally

used with it, a V-shaped cut being made in the stem, and the bud with the leaf attached being used without any wood and struck in fertilizing moss. Mr. Beale claims that such cuttings almost invariably strike, and also that he can get rooted plants from leaves without the bud, though the growth is much slower. The Chrysanthemums can no doubt be increased readily in the first way suggested, and perhaps with leaves only, though the cultural skill and care required in this latter case would be considerable, and the growth would be so weak and slow as not to be of much utility. Mr. Beale believes that this method of propagation will be valuable where a large stock of a new variety is required, but it is difficult to see wherein it is an improvement on layering the flowering stems when stock is scarce and large increase is wanted. The Chrysanthemum is a very accommodating plant, ready to throw out roots from all parts except the flower, and hence it is rapidly multiplied. Detached flowering stems of this plant, if laid in a cold frame and slightly covered with soil, will throw

out strong shoots from every perfect joint, and these can be taken off as cuttings and quickly make strong plants. This is much simpler than Mr. Beale's plan, requires little care, and produces, of coarse, the same number of plants, and probably stronger ones. On New Year's day, to give a practical example, I lifted a stem which had been laid in a cold frame about the middle of November. This had borne a specimen flower and is a foot long, with two weak side shoots, and it had twenty-six shoots in fine condition, though some were quite small. Half the stem gave no shoots, probably because the buds had been taken out in cultivation. Now, it will be seen that one could put this stem in gentle heat, and in a few weeks make a set of cuttings, and these grown along will make others, and as these increase, in a geometrical ratio, I think I am safe in saying that a good propagator would turn out from 150 to 200 plants from this stock by planting-time. Such an increase should satisfy the most exacting.

Because Chrysanthemums are almost necessarily protected by glass in the blooming season, there seems to be an increasing tendency to treat them all through as greenhouse plants. A plant which, after blooming with the greatest profusion, and thus being in a weakened condition, will live out-of-doors in a well drained border, in our climate, with such protection as is ordinarily given to most of the so-called hardy plants, and then "strikes" readily and naturally in a temperature of forty to fifty degrees, is scarcely to be classed as a greenhouse subject. The professional growers propagate and bring on their stock in heat very successfully, but it is not an example for the amateur to follow, except perhaps in the use of very slight bottom heat in striking, when necessary. For the general stock, cuttings in the cold frame will almost invariably root during the winter, and are not so liable to harden up and become worthless, as those grown along in the house. Mildew, however, is the enemy to be watched in this case, and frames should be aired at every opportunity. Most of our growers have discarded early cuttings on account of this liability to mildew. Amateurs will have satisfactory results if they plant their stock-plants closely in cold frames, and protect them well, although a little frost will not injure the plants. Cuttings should be dibbled out in February or March, in the same place. They will soon root, and should be given all possible air, with protection from winds, and planted out at the earliest possible moment.

Elizabeth, N. J.

J. N. Gerard.

The Loquat and the Medlar.

THE Medlar (*Mespilus Germanica*) is a native of Europe, where it is frequently met with in its wild state; but in several of the southern states the fruit is becoming quite popular. In Germany it ranks very high as a common fruit, and large quantities are disposed of on the market-stalls of all the principal cities. When the seeds were first brought to this country it is difficult to say, and there is very little information to be obtained about it from any American books on fruit culture.

The Medlar reached Florida from New Orleans, having been brought there by some of the French Jesuits. It has now been growing in the Florida gardens for thirty years, and, in sections of the upper part of the state, the bushes are frequently met with in a semi-wild state. The fruits on these uncultivated plants have degenerated greatly, and present a strong contrast to those found in the gardens and groves of the white settlers.

The tree is small but handsome, and in Europe it is used for hedges almost as generally as the Osage Orange is employed for like purposes in this country. When the fruit is thoroughly developed and matured on the tree it has a dark brownish skin, with firm, austere flesh. It is of fair size, and very palatable after it has been kept until the first stages of decay, called bletting, has thoroughly softened the flesh of the pulp. It has a rich, subacid flavor then, which is highly prized by many who have become accustomed to the fruit.

The Medlar is usually propagated from seed; but in many sections of the south it has been budded or grafted on the Pear with great success. It has close affinities to the genus *Pyrus*, and by many botanists it is classed as a member of this genus.

The Loquat (*Eriobotrya Japonica*) is a related species to the Medlar, and in many sections of the south it passes under the misnomer "Japan Plum." It is grown quite extensively in the Gulf States, where it reaches its highest perfection; but in many instances it is planted more as an ornamental tree than for the fruit. The tree is a small but handsome evergreen, with thick, leathery, lanceolate leaves, highly polished on the upper side. In the fall of the year the blossoms, of a creamy white color, appear in large terminal spikes, and exhale an

agreeable fragrance, scenting the air almost as generally as the Orange blossoms. In early spring the flowers drop off, and clusters of yellow fruit appear.

The fruit grows in clusters as close as grapes, with a thick skin of a dull pinkish color, and about the size of an ordinary plum. Most of the fruit has a delicious, pleasant subacid flavor; but there is a manifest difference in the size and flavor of the fruit in different sections of the south. There are no distinct varieties described; but some of the trees produce fruit that is very sweet and agreeable to the taste, while others are too acid to be eaten with any degree of pleasure.

The tree is propagated from the seed, and it may be seen in nearly every ornamental southern garden. In the sections of the south where frost is heavy the tree becomes blighted, even while the flowers and fruits are forming, so that it can really never amount to anything as a fruit producer. Going farther south, however, we find that, in the lower counties of Florida the Loquat blooms and matures its fruit during the winter season without interruption from cold, which in the spring offers a tempting feast to all who relish it. The first fruit appears the last of February, just when other fruits are scarce in our northern markets.

New York.

George E. Walsh.

Dracæna Lindenii.—This makes a fine exhibition plant, and has great value for general decorative work, being especially useful for single specimens in vases. It is of recent introduction, and does not differ in its growth from the *D. fragrans*, but the broad, arching leaves of green are beautifully ornamented with a wide margin of creamy yellow, which gives to the plant a very attractive appearance and places it in the front rank of variegated plants. It is propagated easily by the usual method of layering or cutting up the canes, but to make good specimens, fit for exhibition purposes, the heads alone must be used, and these with care will make a fine crop of roots in a few weeks without the loss of a single leaf. *D. Massangeana* makes an excellent companion plant for the foregoing, only differing from it in that the variegation runs through the centre of the leaf instead of along the margin.

Ficus elastica variegata.—Mr. Taplin has not spoken any too highly of the merits of the variegated Rubber plant (ii., 620). We use it for house decoration, and find it quite as hardy as the common kind. We have never experienced any difficulty in rooting the cuttings whether by eyes or by tops. We have rooted a good many lately in a very warm, close frame, with about three inches of fine coal ashes and a brisk bottom heat.

Homalomena (Carmeria) Wallisii is not grown so generally as it should be. It is a handsome plant, belonging to the *Aroideæ*, of low-growing habit, not more than nine inches high, with drooping leaves, six to eight inches long by five inches wide, ovate-oblong, and pale velvety green, copiously blotched with golden yellow. The under surface is dull red. The flowers are rather attractive, the spathe being about three inches long, constricted in the middle and reddish brown, while the spadix is red. To ensure good leaves, however, the flowers should be picked as soon as seen. We grow this plant in the warmest house, potted in a mixture of peat and moss and keep it very wet. Under this treatment it gives great satisfaction. It should be propagated by division.

Kenwood, N. Y.

F. Goldring.

Sowing Seed.—Let me add to Professor Bailey's admirable article that the importance of care in the preparation of the soil is sadly underrated. This care is usually given in proportion to the cost of the seed; that is, a novelty of high price receives due attention, and for this reason rather than for any real superiority, it may excel older sorts. The market-gardeners of Long Island, as a rule, buy their Cabbage-seed of a neighbor who has a reputation for a choice variety; something far superior, he thinks, to anything to be obtained at a seed-house. Market-gardeners pay from twelve to fifteen dollars per pound for this seed, when equally good seed could be bought at a reliable house for three dollars. But the fifteen-dollar seed is the cheapest for the gardener in the end, because he sows thinly in soil prepared with the greatest care. The result is that most of the seed germinates, the plants have sufficient room for development; they do not get "leggy," but are strong and stocky, and in the finely-pulverized, but well-compacted, soil they are well furnished with roots. When these plants are set in the field they do not suffer from the change; their vigor pushes them ahead, they are quickly established, and yield a large proportion of well-developed heads. Low-priced seed, purchased by the same gardener, would have been sown more thickly in loose and coarse soil, where the plants would have been long-drawn, poorly rooted

and without vigor when transplanted. The product from such a beginning will be late, small and of inferior quality. This is not an imaginary case. I have seen seed from the same stock give the best satisfaction, and in other cases none at all. The sole reason for these opposite results was that in one instance the seed was sown properly, and improperly in others. I have more than once noted experiences of precisely this character among the growers of Cauliflower in Suffolk County.

Floral Park, L. I.

C. L. Allen.

Tuberous-rooted Begonias.—Now is the time to sow seed of tuberous Begonias for bedding, or for making showy pot plants this season. Sow in pans in, or rather on (for the seed needs no covering), a mixture of sifted leaf-soil and peat, using the siftings to cover the drainage. Set the pans in saucers, where there must be sufficient water to keep the surface moist by absorption. Place pieces of glass over them, tilted to admit air, rather for protection against careless watering and syringing than for the purpose of keeping them "close." Sixty degrees, night temperature, is sufficient for germination. Gradually remove the glass as the seedlings develop, and prick them out when large enough to handle in soil containing some loam. Increase the quantity of loam at successive stages, and give some shade in the middle of the day as the sun attains power. Plant out in June. A shady situation is generally recommended, but there is a difference of opinion. Save your own seed. In doing this you will succeed best with pot plants.

Wellesley, Mass.

Correspondence.

The Forest-floor.

To the Editor of GARDEN AND FOREST:

Sir.—While I appreciate and subscribe to the main idea of the editorial in GARDEN AND FOREST for December 18th, allow me to call your attention to an expression which may eventually give trouble to those who wish to convince others of the influence of forests on waterflow.

You refer to the spongy condition of the forest-floor, and it is quite an accepted theory that the forest-floor "acts like a sponge, taking up large quantities of water and gradually giving it up to the soil." Even scientific men are apt to use this simile. Now, this is not the action of a sponge, as a simple experiment could prove. While some forest-floors—by no means the majority—do act like a sponge, they are by that very action depriving soil and springs of a considerable share of water.

It is curious that the simile has been used so frequently without an attempt by somebody to first study the action of a sponge. It is simply this: after the sponge is saturated with water, and not before, it will give out water below if more water is added above—that is to say, if the water in the sponge is driven out by pressure of more water. As soon as the supply from above stops, the sponge will stop giving out water from below, except so far as it contains more water than it has capacity to hold. After that, the movement of the water is upward, not downward. Evaporation begins, the upper parts become dry and supply themselves with water from the lower strata by capillary action. Thus, while a spongy floor would do the one thing claimed for it—namely, "retain the water in the spongy mass" and diminish the water which runs off—it would not do the other thing which is implied, namely, furnish gradual supplies of water. This it could possibly do only if the underlying soil strata had become dry earlier than the spongy cover, which is the case only rarely and under exceptional conditions.

The question, then, is, how far does the forest-cover resemble a sponge? Fortunately for water supplies in springs, the resemblance occurs more rarely than the general use of the simile implies. A sponge is a material with remarkable powers of capillarity, as can be seen when placed in a puddle of water, which it will drink up with avidity. Such capillarity in a minor degree may be found in some moss covers, and the consequence is that the amount of water held and afterward evaporated—but not given up to the soil—is quite astonishing. The quantity of water thus retained may amount to from seventy to eighty per cent. of its weight, so that if the moss-cover exceeds a depth of four or five inches it may withhold nearly all the water from the soil, except of heavy rain-falls and snows, and this water is lost by evaporation twice to three times as fast as from other litter; whether an additional amount of water and how much of it will run off superficially or be filtered into the soil, depends largely upon the nature of the latter.

The various kinds of litter, which, after all, form the greater part of forest floors, appear and act, indeed, quite differently from sponges; their capillarity, as can be inferred to some extent from their rate of evaporation, is only small, and they will filter through to the soil much larger amounts of water than the moss (thirty to forty per cent. more). This kind of soil cover, like the moss, does also require a considerable amount of moisture to saturate it, but less than the moss-cover; it loses less by evaporation and gives up more water to the soil.

Altogether, we will have to admit that the forest-floor not only retards the run-off, but it diminishes the amount of water which percolates into the soil. And yet it acts beneficially upon the steady flow of springs by checking evaporation—the greatest dissipator of water supplies. Regularity of flow in the springs, brooks and rivers, as far as it depends upon forest-cover, is due to reduced evaporation under the protection of forest-shade and forest-floor.

The mechanical retardation of the run-off, which the irregularities of the forest-floor and the trunks, stumps and underbrush produce, will certainly tend to reduce the height of freshets in brooks by distributing the flow of water masses over a longer time. But it would be an unwarranted, easily demolished generalization, to say that this retarding influence is everywhere useful in preventing floods of rivers. It may, on the contrary, prove the very source of danger—geological, geographical and topographical conditions being most potent in altering the value of this influence.

It would lengthen this communication too far to argue the influence of forests on floods in general; my purpose is simply to object to the popular idea that a forest-floor acts like a sponge, and to insist that even the admitted retarding influence of the same may not in all cases and everywhere be a benefit.

Washington.

B. E. Fernow.

Mr. Eyerman's Orchids.

To the Editor of GARDEN AND FOREST:

Sir.—During the past three years Mr. Eyerman, of Easton, Pennsylvania, has been making a collection of Orchids which now fill three houses, and a large conservatory has recently been added, containing a fine collection of Palms, Ferns, Cycads, etc., among which Orchids in bloom are tastefully arranged. In this structure I noticed on a recent visit scores of *Lælia autumnalis*, and its showy variety, *Atrorubens*, there being no fewer than fifty spikes crowded with blossoms. *L. albidula* was equally well flowered, most of the plants being on blocks, and bearing unusually strong spikes of well formed and very large flowers. *Lælia Gouldiana*, a very scarce plant, was well represented here by a spike carrying several of its rich purple blossoms, and here, too, were many examples of the charming scarlet-flowered *Sophranites grandiflora*. Some fine Cypripediums of the Insigne type, flowering for the first time, were very interesting, many of them being distinct in character, and among them was a splendidly grown plant of *C. Leeanum superbum*, with twin-flowered spikes, and flowers of great size and exceptionally bright color. Here, too, was a good example of *Vanda cærulea* carrying a dozen of its lovely blue flowers, and near by *Oncidium tigrinum*, with well branched stems laden with rich yellow and chocolate blossoms.

In the house devoted to the Cattleyas and Lælias many choice plants were promising flower. *C. Trianae* and many of its varieties will soon make a fine display, as will the scarce *C. Lawrenceana*, well grown specimens of which were furnished with strong flower-sheaths. *C. Percivaliana* was represented by several large plants, and among the Lælias were quantities of finely flowered *L. anceps*, and its white variety, *L. anceps stella*, carrying three well developed spikes. This variety has hitherto proved somewhat difficult to manage, but Mr. Mænner, the gardener here, has been very successful with it. The plants in baskets are well exposed to the light, and during their growing period receive a liberal supply of water with an abundance of air. In this house the pretty *Angracum Sanderianum* was seen, and some enormous spikes of the yellow-flowering *Oncidium Cavendishianum* were rapidly pushing for bloom. A fine variety of *O. Forbesii* was very conspicuous, its chocolate and golden-yellow flowers growing in quantity on a well branched stem. Fine examples of *Odontoglossum Harryanum* and *Compactia Macroplectron*, with its rosy pink flowers, were in excellent health, and at each end of the house were two handsome specimens of *Cymbidium Lowianum* almost ready to bloom.

In the Cypripedium house, among the rarer varieties, were noticed a grand specimen of *C. calurum* and *C. grande* was in superb health, together with *C. meirax*, *C. plumerum*, *C.*

Mrs. Charles Canham, *C. Barteti*, *C. tonsum*, *C. nitens*, *C. Arthurianum*, *C. Fairrieum* and many others. In a lean-to structure, with a northern aspect, the *Odontoglossums* were in luxuriant health, the majority being of the *O. crispum* type, with stout bulbs and broad-petaled flowers. *O. Pescatorei*, *O. triumphans*, *O. nebulosum* and many more were thriving in a like manner. On the stage at the back of this house were some grand specimens of *Cypripedium insigne* in bloom, about 200 flowers being well expanded, and from the roof were suspended many fine specimens of *Oncidium ornithorhynchum*, *Epidendrum vitellinum*, *Masdevallias* in many varieties, and a fine lot of the pretty *Lalia Dayana*, and its varieties, *Pumila Præstans* and *Marginata*.

Summit, N. J.

A. Dimmock.

Game Covers.

To the Editor of GARDEN AND FOREST:

Sir.—At the annual meeting of the Massachusetts Fish and Game Protective Association, held on January 8th, an instructive address was delivered by Professor B. M. Watson, Jr., of the Bussey Institute, on the subject "How best to preserve and increase the supply of natural food for game birds, and the best means of affording shelter for them."

The address was given in view of the fact that the Association contemplates the importation of valuable game birds of various species from the west and south, to be released in eastern Massachusetts in the spring; and the problem of supplying food and shelter is one of importance to those interested in birds. Professor Watson spoke of the adaptability of various trees, shrubs and grasses. He instanced the fact that many wild birds—quail, grouse and others—frequented the grounds of the Arnold Arboretum, where they are never molested, and where the natural fruits and seeds of various shrubs and plants contribute to their food supply, and he considered that such preserved lands greatly contributed to the welfare of game birds. As the work of introducing and establishing shrubbery for shelter, and fruit-bearing plants must necessarily be slow, the speaker recommends that many waste places—openings in woods, unused pasture lands, etc.—be sown annually with various cereals, particularly Buckwheat, which would yield quickest returns. In Europe for many years past the game and game-preserves have been artificially propagated, and the time has come when we must pursue a similar course or see our few game birds disappear.

The danger from forest fires is perhaps the most serious one to be met, as doubtless more young birds, nests, and even sitting birds, are destroyed by fire each year than can be estimated, not to speak of the wholesale destruction in this way of valuable cover and fruit-bearing vegetation.

Boston, Mass.

John Fottler Jr.

The Mild Winter.

To the Editor of GARDEN AND FOREST:

Sir.—The effect of the unusually warm December was seen here in the opening leaves and swelling buds of many trees and shrubs in the college-grounds. *Spiræa Thunbergii*, *S. prunifolia* and *S. sorbifolia* were putting out leaves. Of the Honeysuckles, *Lonicera flava* and *L. sempervirens* were betrayed into the same fatal activity, while *L. Halliana* had not ceased its autumn growth. Lilac buds were ready to burst, and the blossom buds on Japan Quince, Silver Maple and Cottonwood showed a fullness quite hazardous for this changeable climate. On the 29th of December the temperature dropped to two degrees above zero, and has alternated between that point and sixty degrees above since then.

The following shrubs still hold their leaves on January 7th, and a good deal of their autumn brightness: *Ligustrum vulgare*, var. *buxifolium*, *L. ovalifolium*, *Lonicera Halliana*, *L. fragrantissima*, *Cotoneaster buxifolia* and *Cytisus capitatus*.

It is to be regretted that *Ligustrum ovalifolium* is so tender with us, having killed back nearly to the ground during the past two winters, for its stiff, shining, dark green leaves are conspicuous all through the fall and early winter, acknowledging the frosts only by a slight deepening of color and an occasional purplish tint.

A Garden Conceit.

To the Editor of GARDEN AND FOREST:

Sir.—A charming garden conceit is being carried out in the Royal Botanic Gardens at Dublin by the Curator, F. W. Burbidge, through whose intelligent care these gardens have become among the finest in Europe. "I am making a Bamboo walk," he writes, under date of December 20th, "and I have to plant the margins of a pond and to make a dripping

well with an old Irish cross on it, so that all the maids who visit us may breathe their wishes at the fountain and find them all come true."

G. H. E.

Rochester, N. Y.

Periodical Literature.

It is encouraging to find in a widely circulated popular periodical so strong a plea for the right treatment of a piece of the nation's property as is contained in the January number of the *Century Magazine*. The editorial headed "The Care of the Yosemite Valley," could not be more to the point or more judicious in tone. Beginning with a reference to the policy of "an active member of the Yosemite Valley Commission," who proposes to "cut down every tree that has sprouted within the last thirty years," it says that a crisis in the management of the valley is probably near at hand, distinctly explains why the whole country has as much right as California to express its wishes, and then shows what these wishes should be. The main question to be decided is whether "the treatment of the Yosemite landscape has been intrusted to skillful hands;" and from the results of a recent investigation by the Legislature of California and from numbers of photographs "showing the condition of the portions of the valley before and after the employment of the axe and the plow," the editor concludes that "the valley has not had the benefit of expert supervision." Then he says that though the commissioners, present and past, should not have their good faith impugned, and though "it is no reproach to them that they are not trained foresters," yet their responsibility begins with the very recognition of this last fact; "for, in the absence of knowledge of a professional nature, it should be their first aim to obtain the very best man or men available for this work. No such expert is too good or too expensive, and no claim upon the budget of California should have precedence of this." But there is as yet no certainty that this truth will be acted upon. There is every danger that future commissioners may think of everything else—and especially of facilities for transit—rather than of the preservation of the beauties of the valley. As it is tellingly put: "They may think it is more desirable to improve a trail than to preserve the sentiment for which the trail exists." Nothing could be truer than the following sentences, and we trust they may sink deeply into the minds of the hundreds of thousands whom the *Century* reaches: "To contrive means and methods by which that which is most distinctly valuable to the world in the Yosemite can be perpetuated, and to provide means by which the world can conveniently and effectively make use of it—which means shall be in the least degree possible conspicuous, incongruous, and disturbing to the spirit and character of the scenery—is a problem that no amateur ought to dabble with." Following this editorial essay came three "Open Letters" on the same subject, describing personal impressions received by men who are competent and impartial judges. One is from Mr. George C. MacKenzie, of Wawona, California, who speaks chiefly of the "absolutely shocking use that has been made of the wood-chopper's axe—deadliest foe, in reckless or ignorant hands, of woodland beauty; deadly unless guided by a mind of most rare attainments in the craft of artistic forestry." The writer goes on to say that "there are places in the valley where one is forced to wonder why the axes themselves did not turn and smite the men who were putting them to such base uses," and that "under the system by which the Yosemite is governed there is no saying when the work of the devourer of beauty may not again flourish," although it happened to be checked last year. Indeed, this is the main point. It is useless to try and make individual wrong-doers responsible for the destruction that has gone on. They "are merely the natural fruitage" of the system which intrusts the management of the valley to a board of commissioners who serve for short periods and without salaries, meet only semi-annually, and are chosen without the slightest reference to qualifications of knowledge or taste. Another letter-writer is Mr. R. U. Johnson, one of the editors of the magazine, who, while recognizing certain good points in the management of the valley, describes the terrible injuries that have been inflicted upon it, partly through carelessness, partly through greed, but just as often through an ignorant desire to "improve" upon what nature offers. The third correspondent is Judge Lucius P. Deming, of New Haven, Connecticut, who, again, makes a strong plea for the employment of a trained artist to repair what damage already done can still be repaired, and to guide the course of future work. His letter is not the most sensible of the three—all are equal in this respect—but perhaps the most interesting in its relation of the present state of things and its explanation of the aims that should in future be borne in mind.

Notes.

Elwes' Snowdrop is blooming in suburban gardens.

The loss from Fungus diseases in the vineyards of the Hudson River Valley last year has been estimated by careful observers at from fifty to seventy-five per cent. of the entire crop.

In the note on the discovery of a new station for the Nutmeg Hickory (*Hicoria myristicaformis*), on page 24 of the last number, "Southern California" should, of course, read "South Carolina."

A factory has been established at Mannheim, in Germany, for making a substitute for butter from Cocoa-nut oil. About 6,500 pounds of the substance are daily produced and it is said to be palatable as well as wholesome. It sells at a price equivalent to from twelve to fifteen cents a pound.

It is not known when or why the Chrysanthemum was adopted as the crest of the imperial family of Japan, but it is supposed to have been chosen for its hardiness as a symbol of the antiquity of the dynasty. As used on the Emperor's arms the flower appears in single shape with sixteen rays connected by as many little semicircles.

Mr. C. G. Pringle has lately returned from Mexico, having passed the summer in botanical exploration in the Sierra Madre, and the autumn and early winter near Guadalajara, in the state of Jalisco. He is now engaged at his home in Vermont in preparing for the distribution of the summer's harvest of plants, about 18,000 specimens, representing about 350 species.

In reference to the destruction of wild flowers, Professor Bailey, of Brown University, writes that it is not uncommon to see large baskets of *Arethusa bulbosa* for sale on the streets of Providence in May. Water Lilies are peddled all summer. From their habit and situation they are in less danger of extermination, but these rather rare and local Orchids cannot long endure such onslaughts.

Dr. Edward Palmer sailed from San Diego on the 25th of last month for La Paz to continue his explorations of Mexican botany. From La Paz he intends to travel northward and expects to reach the neighborhood of Guaymas in April. Mr. T. S. Brandeggee sailed by the same steamer for the purpose of exploring the lower part of the California peninsula between Magdalena Bay and Cape San Lucas.

A correspondent in Glenellen, Tennessee, sends us the following memorandum with regard to a large Tulip-tree recently cut down near that place. The smallest diameter across the stump, three feet from the ground, was seventy-eight inches inside the bark, which showed 604 layers of annual growth with only thirty-eight layers of sap-wood occupying a width of an inch and a half. The diameter increased three inches in the thirty years, beginning with the five hundred and thirty-sixth year of the tree's age, and six inches in twenty-five years, beginning at a period when the tree was eighteen inches in diameter.

The *Gardeners' Chronicle* has an interesting article on Cornish gardens and the testimony they offer in proof of the mildness of the climate in certain parts of Cornwall. Certainly Falmouth must be a favored spot on the British Isles, when Agaves flower there, and Bamboos, Palms, Tree-ferns and *Dracænas* flourish, and Pelargoniums cover the entire fronts of many houses. We may add that this vegetation is a striking evidence of the difference in climate caused by ocean currents, winds and other influences on opposite shores of the Atlantic. One can hardly imagine Bamboos in Labrador, and yet Falmouth is nearer the North Pole than the southern part of Labrador.

About ten years ago the Austro-Hungarian government planted the sides of a very exposed stretch of railroad, nearly a mile and a half in length, with hedges of the Provence Rose. The hedges have since reached a height of about six and a half feet and a breadth of half as much, for it is a peculiarity of the Provence Rose to interlock its branches and twigs. A living wall has thus been formed which effectively protects the track from snow-drifts, while a neighboring stretch, where the Rose could not be planted, is so deeply buried at every snow fall that it costs much labor to clear it. The first cost was very small and it is believed the hedges will live for thirty or forty years.

Paris will be permanently benefited by the International Exhibition recently closed. The gardens formed on the once naked expanse of the Champs de Mars will remain, and will be extended over spaces covered during the summer by a

multitude of minor structures. The two palaces of the arts will be preserved, and likewise the immense machine gallery, and the latter, it is announced, will be held in readiness for live stock, agricultural and horticultural exhibitions. Under such an unrivaled expanse of glass wonderful shows will doubtless be arranged, especially as a track 300 yards in length and 100 yards in breadth will alternately serve for the exercising of animals and the disposal of flower-beds.

A writer in the *Pacific Rural Press* proposes to use the blossoms of Orange-trees for perfume, and thus realize one more profit from the trees. Every Orange-tree, he argues, has at least ten times as many blossoms yearly as can or ought to bear fruit. At least three-fourths, if not seven-eighths, of the blossoms can be picked off and worked into perfumery without damage to the orange crop. There is a place on the Mediterranean called Grasse, lying near Genoa, where the manufacture of perfumery from orange-blossoms is a specialty—the trees being cultivated for that purpose. Some of the perfumes are exceedingly expensive—one kind of oil made from the orange-blossom, selling at the rate of \$300 per gallon.

At the suggestion of Professor Maynard, of the Massachusetts Agricultural College, Dr. Jabez Fisher, of Fitchburg, girdled one of the two bearing arms of each of sixty Concord Grapevines on the 5th of July last, taking out a ring of bark half an inch long near the trunk of the Vine. As a result the grapes on these arms showed color six days before those on the opposite half. They were fit for market September 20th, or some ten days in advance of the others, and the berries were much larger and sweeter. The gain in earliness makes a great difference in the price of the fruit, and later varieties could be grown when thus treated, which would not ripen if left to themselves. The grapes are larger and more attractive, and this would counterbalance the softness of the berries, a condition which the girdling seems to cause.

Did we go back to farthest antiquity for our holiday customs we should not hang up the Mistletoe until a week after Christmas. When the Druids had carefully cut the parasite from its Oak with golden shears and dropped it into the white cloths held to prevent it from touching the earth, it was distributed to the people on the first day of the new year. Its chief offices were supposed to be the conferring of fertility and of invulnerability to poison. With the advent of Christianity the old reverence for the plant remained in a diluted form. Its use was transferred to Christmas, but it was still hung from the ceiling as it had been in days when a bit that fell to the ground was supposed to portend ill luck. Until that happened it was sacred to the beneficent Freya, but the ground was Loki's empire and Loki was the promoter of all misfortune.

A correspondent sends us a photograph of the great Silver Maple (*Acer saccharinum*) growing on the meadows at Northampton, in Massachusetts, which Emerson mentioned in his "Trees of Massachusetts," page 489. This tree, according to Emerson, in 1837 had a trunk circumference three and a half feet from the ground of twelve and a half feet. Fifty-two years later the trunk girths at the same distance from the ground seventeen feet four inches, an increase of four feet ten inches, equal to an annual average increase in diameter of .355 of an inch. This is remarkable growth, considering the probable great age of the tree, which, judged by the vigor of the branches as shown in the photograph, promises to survive for many years more, although the trunk shows a large cavity extending through it near the ground from one side to the other. Several of the large branches too have been destroyed.

Much has recently been said in these columns about the proper arrangement of trees, shrubs and vines close to country houses. An excellent example of successful treatment may be seen in a colored plate, accompanying the issue of *The American Architect and Building News* for December 28th, which represents a house owned by Mr. Herbert Jaques, at Chestnut Hill, near Boston, and recently built by Messrs. Andrews and Jaques. A group of tall Elms, stands just near enough to the end of the house to shadow without darkening it; and shrubs are grouped beneath the trees and carried well up to it, where they blend with the vines that are beginning to clothe it. Behind a shed at the opposite end of the house rises a smaller Elm, and the front of the shed is masked by gracefully growing shrubs. Except where the gravel curve actually meets the doorway, a space is left for low shrubs and vines. The lawn that fills the foreground of the picture would be improved by the removal of its few isolated shrubs and saplings; but with this exception, house and planting alike are models of their kind.

The Money Value of Rural Improvements.

ONE of the strongest considerations in favor of preserving the forests in mountain regions like those of New Hampshire is that they offer irresistible inducement to people in the city who are looking for summer resorts. Many people have come to consider a summer residence among the hills as essential to their comfort as a winter home in the city; and the growing practice among those who cannot afford to support more than one establishment of spending some weeks or months away from the confinement of city life makes it a matter of importance that provision should be made for those who find health and pleasure in the woods and amid the scenery of wild nature.

It would be hard to estimate the direct pecuniary advantage which a state like New Hampshire derives from this tide of summer travel which flows toward her mountains all summer long. Every one of these visitors, in some way or other, helps the entire community upon which he depends for a certain time each year for his pleasure and subsistence; and it would not be difficult to prove that the actual and prospective revenue derived from this source is so important that the value of the material products of the forests of the state, even under the wisest management, would be insignificant by comparison.

But it should not be forgotten that there are thousands of people from the cities who, instead of resorting to mountain and forest regions, or to the shores of the ocean, prefer to spend their summers in quiet country villages and farm-houses. Of course it is quite as much to the interest of rural communities to make their neighborhood attractive as it is for the owners of sea-coast and mountain-land. It is true that this should not be considered as the chief reason for efforts to improve the appearance and add to the convenience and comfort of country towns. Societies for rural improvement accomplish a good work when they brighten in any way what is often the dull side of country life. Every attempt to beautify the surroundings of country homes and make them attractive brings its own reward in the happier life of those who inhabit these homes. But apart from this there is a tangible business advantage to be

gained by country villages when they are made specially attractive to city visitors; and this profit accrues not to the villages alone, but to all the surrounding region, when the farm-houses are open to paying occupation, and a market is provided for the products of the farm. It happens in this way that to the population of a large district it is a matter of actual profit to have the neighboring villages and towns made attractive.

The first work in this direction is to improve the roads so that there is some pleasure or at least some comfort in traveling abroad. A visitor who reaches a village over a muddy and rough highway receives no good impression of it, and as the road is also the last thing as well as the first thing which attracts his attention, bad roads are among the most repellant and disagreeable features which any community can present. But where the roads are smooth and hard, with little dust and mud, and where good foot-paths abound, a strong inducement is presented to those who love to pass much time in the open air. Of course this is but one feature of the reform in any community. Shady walks, roadsides clean and bordered with shrubs where this is practicable, farm-yards free from unsightly objects, gardens neatly planted and kept—all these things not only delight the eye as manifestations of beauty and order always do, but they suggest a cleanliness and propriety in all the details of life and a proper regard for health and comfort; they give assurance of good drainage and pure air and all other conditions which make a sojourn in the country desirable and beneficial.

Now, inasmuch as all the inhabitants of a given district are interested in matters of this sort, combined action is naturally suggested. The influence of personal example is undoubtedly great, and many a man, by the proper ordering of his own grounds, has set a pattern which has been followed by his neighbors until an entire community has been regenerated. But after all, these matters can be much more efficiently carried on if it is done in an organized way. Many a town in New England and in the middle states has become prosperous because wealthy men from distant cities have bought lands near by, which have been transformed into beautiful parks, stocked with well-bred cattle and horses. All this was brought about because in the beginning there was unity of purpose in the community to make the town attractive, and transient guests were induced to become permanent residents. Examples like this should be an encouragement to all country neighborhoods and especially to such as have some natural advantages. There will be no abandoned farms in a region where there is associated effort for rural improvement. Such effort cannot fail, in any event, to add to the comforts and pleasures of rural life, and it is more than probable that it will insure a more substantial return in actual revenue than any other equal outlay in whatever direction it is invested.

In every state where there is not already a law to that effect, the friends of the forests should, as soon as possible, secure the passage of an Act restricting the time and method of burning brush. Brush fires are the principal cause of damage to the forests in the eastern and thickly settled parts of the country, and it is hopeless to try to check forest fires unless this evil can be restricted. The notion that a man has a right to do as he pleases on his own land would be well enough, perhaps, if one man owned all the land in the country and were its sole inhabitant. Then his doing as he pleased could injure only his own property. When there are but a few people in a great forest region they are naturally apt to acquire the habit of indifference to the consequences of their actions, because there is often no one to be injured by them or to call them to account. As population increases the habits of careless freedom which were formed in earlier times are still followed, but under the changed conditions they work great and increasing injury.

A man has no right to liberate a destructive force on his

own premises, when it is certain to pass beyond his control, and destroy the property of his neighbors. And yet brush fires are usually set in times of drought, and very often under circumstances which render extensive injury almost certain. Dwellings and other farm buildings, with crops and stock, are often consumed by a fire which was started to burn a little rubbish; and although the burning of a house attracts more attention, it causes far less loss than that which results from the destruction of extensive tracts of forest or woodland. It is impossible for men to live together in civilized society unless they recognize the necessity of submitting to a little control in the interest of the whole community. Necessary restraints and orderly methods are a benefit to all, and as an increasing number comes to be affected by the action of each individual, the sense of personal responsibility should be developed so as to correspond with the more complex conditions of life. The present inconsiderate and lawless method of setting brush fires is a constant menace to the whole community wherever it is practiced. Values to the extent of many millions of dollars are destroyed every year in this country by the fires thus started. Freedom is but one side of life in civilized lands. Order and law are quite as necessary, and they subserve the interests of all. We need in this country a clearer recognition of responsibility for actions which are injurious to others. Want of intention to injure should not excuse carelessness and indifference. Every state should have on its statute books a brief and plain enactment providing for a practical and effective supervision of the matter of firing brush, prescribing the time and conditions for work of this kind, the method by which the law is to be enforced, and the penalties for its violation. Such a law is a matter of great convenience, as well as of economy, in every orderly community, because it enables the citizens to co-operate with each other for their own protection and for the safety of all; and legislation for this object is especially necessary in those states which include considerable areas of forest.

The Decorative Use of Flowers.

IN the decorative use of flowers the two qualities of color and form (or mass) are both to be considered. The first appeals much more strongly to the ordinary sense of beauty and the domestic side of life; but the elegance of certain plant-forms is fully recognized and is instinctively used in the decoration of large interiors, especially of those which have at least a semi-public character. The statuesque growth of the Palm and the delicate arches formed by the spring of tropical Ferns are essentially in harmony with architectural surroundings, and it is a genuine artistic instinct that has, in a manner, dedicated them to the decoration of churches and large halls. Indeed, it is an instinctive sense of fitness which has prescribed the unwritten law that form shall be chiefly depended upon in the decoration of interiors of architectural dignity, and color in the decoration of the home.

Beautiful combinations of color are more generally felt and accomplished than beautiful combinations of form, because the appreciation of form depends upon a much more cultivated intelligence. It is thoroughly understood in Japan. Any thoughtful observer of Japanese art has noticed—especially in the relief decoration of bronzes—that flowers and plants are used absolutely as models, not as mere themes, for decorative designs. Each flower is used singly, at its best and most perfect development of form; and the jar or vase which holds it is selected to carry out the beauty of its lines. This beauty of line which is so effective when applied to ornament is even more effective in nature and can be made to tell with great success in its relation to the decorative grouping of flowers even in the home. Decorative grouping may include the best possible effects of both form and color, and it is for this combination that the true lover of beauty will strive. Anyone with a good memory for color effects, enriched by many a lovely result of accidental grouping—and possessing also that instinct to select among such lessons which we call taste—is well equipped for using flowers for decoration. These memories of successes in time become principles, so that one comes to use contrasts and combinations in flower tints as unerringly and unhesitatingly as a true artist blends or opposes colors upon his canvas.

In the decoration of a room, as a rule, all masses of delicate color should be arranged or placed in strong lights. If for a daylight effect, they should be placed nearest the windows, where no dense shadow will blot out both form and tint. White flowers are best when placed in immediate contrast with a color which reflects, as in this way the white really gets the value of gradation of tint.

Each flower should be able to detach itself from the mass, so as to give shape as well as color. This applies principally to flat masses or banks of flowers which may be most artistically arranged as to color and yet lose immensely in effect if the flower-heads are not allowed to spring, as they would in nature, against some background of foliage or atmosphere.

In all masses or groups of flowers, the best effects of color are made by shading and gradation, using the same variety of flower in different colorings, white warming into rose and rose into carmine, or pale lemon-color deepening into yellow, yellow into orange and orange into sienna or Damascus red, Blues on blues, lilac-purples on blue-purples: these are harmonies with which every flower-lover is familiar, but their effect can be wonderfully intensified by contrasting them with each other, or by different considerations of background and surrounding. A careful leading up of color in the jar or vase which holds the group is of great importance; choosing one which has the same general tone as the flowers but darker, and repeating the color again, but in a lighter tone, in some drapery or other object in the background. To illustrate this, suppose a jar of blood-red Tulips splashed and spotted with red, placed in some shadowy corner of a room, where a brilliant effect is needed. They should stand on a level with the eye, upon a shelf or piece of furniture which is itself dark in color. The jar or vase—which should be rather large in proportion to the mass of flowers—may be of wine-red or liver-colored lustre, or of the red De Morgan lustre showing orange flakes of light from its reflections of the Tulips. The mere added bulk of color is a gain from the decorative point of view, while the repetition of it in a reflecting surface is still another point gained, this glitter giving value to the flesh-like quality of the flowers. If something in drapery, in tones of reddish-ochre or pure yellow, can be drawn in folds behind both jar and flowers, and can fall in long lines below them, the largeness and breadth of effect is still further increased. One can see at a glance how much greater the decorative effect produced by this treatment would be than could possibly be obtained by all these things separately used.

Jars of metal—brass, copper and silver—are universally appropriate to the decorative placing of flowers, and this because of their reflecting quality, which repeats any color massed above them. But the inherent color in metal is more valuable for its contrasts than for its repetitions. Blue flowers in a bowl of burnished brass, with brown-gold draperies behind and beneath them, are a joy forever; and any one who has ever arranged a group of pink Orchids in a classic silver vase, reflecting all their elegance of form and changing beauty of color from the mirror-like breadth of a salver placed below them, will not soon forget the lustrous pearl-like quality of their beauty. Such an arrangement finds its proper environment in a white drawing-room or upon the satiny linen of a dinner-table.

As an illustration of the value of appropriate color and place in the surroundings of flowers, imagine how unlovely this classic vase, with its pink and pearly Orchids, might be if placed against a deep, India-blue curtain, in some dark library or sitting-room. All its delicacy and elegance would be worse than lost—they would count against it as a decorative effect. In such a room one should draw the heavy curtains partly away from the window, and, half against the curtain and half against the light, place a great round brass jar crowded full of bright blue Larkspur, or single Hyacinth, or Canterbury Bell, or any other strong, pure-blue flower. Or one might stand a tall, cloudy-blue porcelain vase against the light, in the middle of the window, fill it with stalks of blue Fleur-de-lis and spiky blue-green leaves, and get an effect like a panel of stained glass.

Solid color is always an advantage in a flower-holder, and few things are more effective than the clay colors—the reds and browns and ochres, and, more than all, the greens one sometimes finds in Spanish and Indian water-jars. All flowers are beautiful in green jars, and it is a pity that they are not more easily procurable, or that they are not attempted in some of our potteries. In fact, large, well shaped and well colored jars, of coarse and cheap clay, are greatly needed in the decorative market. Rich brown, two-handled cooking jars come as near the sort of thing needed as can easily be procured,

and any one who has arranged in them long running branches of yellow and maroon Nasturtiums, or the yellow glory of the Black-eyed Susan, will understand their value.

Endless examples of beautiful arrangements of flowers might be given, and endless rules for such arrangements, but it must be remembered that, to make a house or a room beautiful with flowers, every peculiarity of furnishing, color and light must be taken into account, and that any arrangement, beautiful in itself, may lose all its value from an inharmonious setting.

New York.

Candace Wheeler.

The Nettle Tree.

THE Nettle-tree (*Celtis occidentalis*), known also as the Sugarberry, Hackberry and False Elm, is one of the widely distributed trees of the American forest; indeed, with the exception of the Red Cedar and of the Box Elder, there is no other American tree which grows over such a wide territory or flourishes under such varied climatic conditions. It is very common in some parts of the country, and in others is so rare that to most people its name conveys no idea whatever. In New England, where it is found only in localities remote one from another and never anywhere in large numbers, very few persons know of or can recognize this tree. It is more common on the banks of the Hudson, where it grows quite commonly along the roadsides and by fences, and is sometimes a feature in the landscape; farther west it grows to a larger size and is much more common, and in the forests of the lower Ohio Valley it is one of the largest and most common trees, and is as familiar to the people of that part of the country as it is strange to the inhabitants of New England.

The Nettle-tree belongs to the same family as the Elms. It differs from the Elms, however, in its fruit, which, instead of the membranaceous dry samaras of those trees, is a globular drupe with a thin pulp surrounding a stony seed. The flowers are very much like those of the Elm, except that the male and female organs are generally produced separately, and that the females have one instead of the two ovules of the Elm and that instead of appearing before the unfolding of the leaves they open with them. The flowers, crowned with their two long recurved stigmas, are green and quite inconspicuous, and generally escape the notice of persons who are not looking specially for them. The fruit,* which hangs late into the winter from long slender stems, is as large as a pea and deep orange colored when fully ripe. The dry flesh between the thick outer skin and the stone or seed has an insipid but rather agreeable flavor, and is devoured by many birds.

The Nettle-tree, as might be expected of a plant subject to such varied conditions of soil and climate, varies greatly in different parts of the country, and botanists have at different times believed that it represented several different and distinct species. The reproductive organs, however, are identical in all the various forms the tree assumes, and the differences are differences in habit, and in the leaves, which vary greatly in size, shape and texture. These different forms, however, seen together in large numbers, all pass from one into another, so that it is impossible to find any fixed character of leaf by which it is possible always to distinguish the different forms which have been considered different species. The bark of the trunk in all the forms presents the same general appearance; it is ashy gray, and covered in the case of old individuals with thick discontinuous corky ridges, sometimes an inch deep and half an inch thick.

The Nettle-tree, as it grows in New England, is a low, round-headed tree, fairly well represented in the illustration on page 43, which is the portrait of a tree growing close to the shore on Squantum, a point of land running out from the city of Quincy into Massachusetts Bay. This particular specimen has always grown with sufficient

room for the development of its lateral branches. This, and the fact that it has been exposed to the sweep of the wind, has changed its habit somewhat and shortened and thickened its branches. On the banks of the Hudson the Nettle-tree is an entirely different looking object, with a short, slender trunk, and long, graceful, pendulous branches; west of the Alleghany Mountains, which is the true home of the species, it reaches occasionally, according to Mr. Robert Ridgway, whose paper on the native trees of southern Indiana and Illinois (published in the *Proceedings of the National Museum* for 1882), is one of the most interesting and instructive contributions to American dendrology ever written, a height of 120 to 130 feet, with a tall, slender trunk, 80 feet sometimes to the first branches, and

Fig. 7.—*Celtis Occidentalis*: Mississippi Valley.

often comprising three-quarters of the total height of the tree. A little farther west, on the dry Ozark hills of Missouri, it is reduced to a low shrub three or four feet high only, but always with the same flowers and fruit; in the valley of the lower Rio Grande in Texas, and in the mountain valleys of the Sierra Madre in the adjacent parts of Mexico, the Nettle-tree has a short, stout trunk, with a wide head composed of long and exceedingly pendulous branches, the whole forming a tree which no one looking at it from a distance could believe was the species of the Massachusetts coast or of the Indiana forests. Farther west again, in the arid region of western Texas, in Arizona, and in Sonora, it generally has short, stout, upright branches and a totally different habit.

* I.—The fruit may be seen, with the aid of a magnifying glass, hanging on the branches of the tree in the illustration on page 43.

The leaves of the Nettle-tree vary more than its habit of growth under the influence of its climatic environment, although certain characters, especially the arrangement of the veins and the nature of the pubescence which clothes them always in their young state, are common to them all. The trees produced on the fertile soil of the

rather coriaceous leaves with entire margins, very common in the southern States, has been described as *C. integrifolia* (Fig. 9). This form passes, however, into forms with leaves more or less serrate. The leaves of the dwarf form (the *C. pumila* of botanists, Fig. 10) are generally not more than two inches long when fully grown and are often much

Fig. 8.—*Celtis occidentalis*: Massachusetts.—See page 39. 1. Fruiting branch. 2. Flowering branch.

Mississippi Valley have large, membranaceous leaves with deep sharp serratures (Fig. 7, p. 39) quite smooth on the upper surface and only slightly rugose on the lower. This is the form which has been called both *Celtis Mississippiensis* and *C. crassifolia*. On the New England trees the leaves are smaller, and generally narrower, thinner, less coarsely serrate, glabrous or only slightly rugose on the upper surface (Fig. 8). The form with narrowly acuminate, smooth,

smaller; they are generally entire, although sometimes deeply and sharply serrate. The leaves of the Rio Grande form (*C. Berlandieri*, Fig. 11) are acute, with a long, slender point often somewhat falcate and quite glabrous on the two surfaces. The most distinct of all the varieties is that of the arid south-west, the *C. reticulata* of Torrey (Fig. 12). The leaves of this variety are thick, coriaceous, entire, conspicuously venulose, rough on the upper surface, and

Fig. 9.—*Celtis occidentalis*: Entire-leaved form.Fig. 11.—*Celtis occidentalis*: Lower Rio Grande Valley.Fig. 10.—*Celtis occidentalis*: Dwarf form.Fig. 12.—*Celtis occidentalis*: Arizona.

rugose on the lower. This plant taken by itself might well be mistaken for a distinct and well marked species, but it is connected with the entire leaved form of the Mississippi Valley by innumerable intermediate forms which vary in the thickness of their leaves in proportion as the region in which they grow is unequally and insufficiently supplied with moisture.

The range of the American Nettle-tree is from the valley of the St. Lawrence to eastern Oregon, and to Florida, northern Mexico and south-eastern California.

The wood of the Nettle-tree possesses a good deal of

value, and it is destined, as better known woods become scarce or are exterminated, to be used more in the future than it has been in the past. It is strong, not very hard, and easily worked. The color is a pleasing light yellow, but its appearance is injured by the large number of open ducts which mark the layers of annual growth. It has always been used for fuel, as the tree is easily cut and the wood splits well; and of late years it is coming into use in some parts of the west for the manufacture of cheap furniture.

The ornamental value of the Nettle-tree is great; the

habit is good and often exceedingly graceful; the foliage has a bright cheerful green color, and the leaves remain fresh and green on the branches long after those of nearly all our other native trees have fallen. They drop finally without any marked change of color. This tree grows very rapidly; it is free from serious attacks of insects, and it is admirably suited to plant as a street or roadside tree. It will thrive in all sorts of soil and in all exposures, still there are few American trees which have been so seldom planted, or whose beauty or value are so little known or appreciated.

The illustration on page 43 is from a photograph for which we are indebted to Dr. William Herbert Rollins, of Boston. The illustration serves to emphasize what has been said more than once in these columns, that trees in winter possess peculiar beauty, and that to know them well and to appreciate them they must be seen at this season of the year as well as in the summer. Foreign Correspondence.

London Letter

THE WEATHER PLANT.—About a year ago we were informed by the London papers that Mr. Nowack, of Vienna, had discovered a wonderful property in the leaves of the plant whose seeds are commonly known as "Crab's-eyes," and which is known by the name of *Abrus precatorius*. Like a great many plants belonging to *Leguminosæ*, the leaves of the *Abrus* perform many extraordinary movements under the influence of light, etc. Whatever the cause may be, no one can doubt that the movements of the leaves of this plant, of the Sensitive Plant (*Mimosa*), of the Telegraph Plant (*Desmodium*), of many *Acacias*, *Bauhinias*, and other *Legumes*, have not yet been properly accounted for. Charles Darwin made many experiments and observations on these very movements, and finally concluded that "leaves which sleep continue to move during the whole twenty-four hours." He also demonstrated that there is a continual motion going on, although not generally perceptible, in all plants at all times. The *Abrus* is not the most striking amongst plants whose movements are exceptionally palpable; but Mr. Nowack, after long observation, concluded that in them we possess a "weather indicator" much more trustworthy than any meteorological instrument whatever. He declares that "its sensitiveness to atmospheric and electric influences may be turned to practical account for forecasting the local weather, with truly marvelous precision, forty-eight hours beforehand, and likewise earthquakes or subterranean disturbances, both at a distance and locally, with respectively three to eight days previous notice." An apparatus in which the plants were to be grown was patented by Mr. Nowack, and this, along with his plants, he brought to Kew in July last, with a letter of introduction from H. R. H. the Prince of Wales.

The Directors of Kew naturally afforded every facility to Mr. Nowack in his demonstrations, and Dr. Oliver, one of the best of the younger school of physiological botanists, undertook to watch and check Mr. Nowack's work. The result is about to be published in the *Kew Bulletin*. That the plant is of absolutely no value as a weather indicator is proved by the statistics given in Dr. Oliver's report. Mr. Nowack's prognostications were scarcely ever nearly right, and whatever the cause of the movements it is proved that they are not produced by the weather of the day after to-morrow. Mr. Nowack may plead that weather in England is made up of samples, and no plant, nor yet instrument, however nicely arranged, could foretell weather here. The movements of the leaves of the *Abrus* are influenced by changes in the intensity of light, changes in atmospheric humidity, and changes in temperature. So also are the movements of many other *Leguminous* plants; but why their leaves should move so conspicuously whilst those of other plants under the same conditions show no perceptible movement remains an unsolved problem.

The idea that some plants in their movements foretell the weather is not new. At the end of last century, Ruiz and Pavon describe the movements of *Porlieria hygrometrica*, a Chilean *Zygophyllaceous* plant, not unlike a *Mimosa*. These movements, they say, foretell the weather by closing their leaves in the evening half an hour before sunset if the morrow is to be dry, and an hour before sunset if it is to be overcast and tempestuous. This plant is in cultivation at Kew, and Dr. Oliver has found nothing in its movements to support the above theory.

A GARDENER'S PROBLEM.—Under this title the Director of Kew has communicated to *Gardeners' Chronicle*, a paper on horticulture, which he declares is "essentially an empirical art." This statement the editor of that journal finds fault with on the ground that it is too absolute, and "very discouraging to those who believe that practical horticulture has a right to look to vegetable physiology and anatomy for guidance and profitable suggestion, and, moreover, that it will not look in vain." I need not attempt to reproduce Mr. Dyer's arguments here; but I may say that, however discouraging it may appear, there is no getting away from the fact that horticulture, pure and simple, high-class horticulture, too, obtains practically very little help from the professors of physiology or any other department of botany. An exception might be allowed in favor of those who supply names for garden plants, but the name of a plant is of no assistance in its cultivation, and there are dozens of first class cultivators whose knowledge of nomenclature would be called wofully deficient by the systematic botanist. On the other hand, there are many good gardeners who know a good deal of botany; but they are no better cultivators on that account. I use the term gardener only in the sense of a cultivator of plants. The gardener as an educated man is another question. It would not be difficult to name a dozen men, past and present, who stood, or stand, head and shoulders above their compeers in a knowledge of gardening art, but who never looked for any assistance from the physiologist, and probably never wanted it. The fact is, as Mr. Dyer states, good gardening is the outcome of experiment, and he is the most successful cultivator who is the most thoroughly acquainted with the best methods—*i. e.*, the best results arrived at by experiment on the part of gardeners generally. Take as an example any plant newly introduced, whose cultural requirements are unknown. *Nepenthes Rajah* was introduced by Messrs. Veitch about six years ago. They knew where it came from, and no doubt were well acquainted with the conditions under which it grew when wild.* The plants of *N. Rajah* were distributed, and many were lost through wrong treatment, even by those who grow *Nepenthes* well. It looked as if this grand Pitcher Plant would prove incapable of cultivation, when lo, the information came from Glasnevin, the garden of many important horticultural achievements, that the cool conditions afforded by the Masdevallia, house suited exactly this *Nepenthes*. Physiology would not have been of the slightest avail if called in here, nor would anything have equaled the empirical act of Mr. Moore when he removed a *Nepenthes* from the hottest to the coldest house and watched the result. It often proves the case that some outsider, working in utter ignorance of the conditions provided by Nature for a particular plant, has discovered the best method of culture by accident, some would say, but at any rate, by purely empirical means. Propagation, one of the most important departments of horticulture, neither seeks nor requires assistance from the botanist, and it is questionable if the botanist could help toward the discovery of the most suitable method for the multiplication of any plants. So far as I know he has not done so yet.

Botany, however, explains a great deal of what the gardener does, and in this manner it may be said to help him. The man who understands somewhat the nature of what he is doing is superior to the man who works blindly by rule of thumb. The fact remains, however, that horticulture goes its own way, and by experimenting in all directions discovers the needs of most plants in a manner that often astonishes the botanist. It may be heresy to say so, but the scientific man who knows nothing of horticultural art, is oftener a hindrance than a help to the gardener; and it is not until he has tried to grow plants by the light of his science, and not according to the rules of horticulture, that he discovers with Professor Forster "that there are more things in the plant and in the soil than are dreamt of in the latest philosophy of our newest botany," and the gardener who aims only at fitting the plant and the conditions at his command, so as to make them agree, obtains better results than could be got by the most minute research in the botanical laboratory.

This subject leads one to the consideration of horticultural schools, which are occasionally recommended as affording that kind of training most desirable in a gardener. During the last ten years I have been brought into contact with some

* Mr. Burbidge, who found this plant in Borneo, thus writes of it in his charming book, "The Gardens of the Sun," p. 100: "On open spaces among rocks and sedges the giant *Nepenthes Rajah* began to appear, the plants being of all sizes and in the most luxuriant health and beauty. The soil in which they grew was a stiff yellow loam, surfaced with sandstone grit, and around the larger plants a good deal of rich humus and leaf debris had collected." Still higher up the same mountain Mr. Burbidge found *N. villosa*, and it is remarkable that whilst the latter thrives only in the hottest and moistest stove, *N. Rajah* must be treated as a cool plant. Who would think of attempting to grow *Nepenthes* in a "stiff yellow loam?"

Fig. 13.—*Celtis occidentalis*: Coast of Massachusetts.—See page 39.

hundreds of young gardeners, who have been employed here at Kew, and with scarcely an exception I have found that those men who had been trained in the sciences, in professed horticultural schools, were much inferior as gardeners, *i. e.*, cultivators, to men who had devoted themselves to the study of the art of gardening, and practised it in good gardens. Gardening is instinctive, and a man must love plants for their beauty, not as botanical curiosities or anatomical studies, if he is ever to shine as a gardener. The best gardening school is a good garden, where what is done is done earnestly; and the best gardeners are men who study first the plant as a thing to be grown well, and make it their special business to be con-

stantly on the look out for "wrinkles" which shall help them in their art. As a rule, when a man begins seriously to count stamens and cut sections, he has started on a road that will take him away from gardening, if he is not careful; it may lead him to something that is considered higher than gardening, which, however, is beside the point. *W. Watson.*

London.

[No doubt it is true that scientific study alone will not suffice for the equipment of a practical cultivator; but few persons will deny that it is possible to add with advantage to practical training in the art of gardening some knowledge of the sciences upon which it rests.—Ed.]

Cultural Department.

Grafting.

SOME time ago the London correspondent of GARDEN AND FOREST spoke of the controversy about grafting carried on in *The Garden* and expressed the hope that some American comment would be made on the subject, especially because grafting must have been tested here on a gigantic scale. I had already procured some figures from Mr. C. A. Green, secretary of the American Nurserymen's Association, which I quote: "We have record of five thousand nurseries in the United States, and I estimate that there are five thousand not recorded. Ten thousand nurseries, many of them very small, I estimate, average ten thousand trees yearly, giving one hundred millions of trees propagated annually. For the past fifty years, perhaps twenty millions annually would be within limits, giving a total of a thousand millions in fifty years." These trees have been scattered all over the United States, an area three thousand miles in diameter. Sixty millions of people in America, and perhaps some thousands in Europe, eat annually of their fruit. They were all grafted trees, many of them double-grafted, and so satisfactory has been the process that American nurserymen will continue to graft and American fruit-growers persist in planting them, and yet these trees are what some able writers in the English press stigmatize as "rubbish;" one eminent writer going so far as to assert that "grafting is always a make-shift and often a fraud."

Now I do not care to show how impracticable are the notions of some of these writers who advise a "return to the old plan of hillock layering" instead of this "fraudulent" practice of grafting. I merely wish to state that universal experience has proved that this wholesale condemnation of grafting is baseless. The nurseryman who tries to unite a graft with an unsuitable stock will not succeed, simply because he does not know his business, but when an appropriate stock is chosen for a graft, and both are properly prepared, there is no evidence to show that the tree will not be as long lived and as healthy as a seedling on its own roots.

Mr. Temple, of Cambridge, who was in England while the controversy was at its highest, stated that the sole reason for the use of grafting has been its cheapness. Now if trees can be propagated equally well and more cheaply by grafting than in any other way, that would be an ample justification for the practice. But the fact is that grafting serves many other useful purposes. No doubt the writer of the above is aware that American vines are now largely grown and sold in Europe (see GARDEN AND FOREST, vol. 2, page, 555) as stock upon which the more delicate old-world varieties of grapes are grafted, and that in many regions vine-culture has been saved by this process because the phylloxera does not injure the strong roots of the American vines. It is well known, too, that many ornamental trees do better when grafted than they do on their own stock. *Magnolia glauca* is greatly improved by grafting it on *M. acuminata*, and no one would be so foolish as to layer *M. parviflora* or any other of the new sorts. Mr. Burbidge asserts that he would as soon think of grafting a cabbage as a coniferous tree, and yet he can find thousands of grafted conifers in England which have grown with great vigor and beauty for forty years. In this country seedling Norway Spruces are old and brown and dishevelled in thirty years, while the Oriental Spruce, grafted on this same Norway stock, is in full vigor and beauty.

Mr. Temple states that he has seen acres of grafted Chinese Magnolias with all their buds killed in a hard winter. I have never seen acres of living or dead Magnolias here, but I have seen enough to know that Magnolias properly grafted, planted and cared, for are as sure to grow for twenty years as are Apple trees or Pear trees.

The whole gist of the matter seems to lie in the question whether a perfect union can be formed between a graft and the stock. This is a question in physiological botany which I am not capable of answering scientifically; that is, I have never made, nor am I able to make, the proper microscopic and other investigation which is needed to demonstrate that the union is absolutely perfect; but as a matter of practice I think that no one who has had years of experience will hesitate to say that when trees are properly grafted they show no less vigor than seedling trees and are quite as likely to be long-lived. Of course if one selects for stock and cion plants which are not closely related, or pays no proper attention to the condition of both when the grafting is done, or performs it in a clumsy way, failure will follow. This only proves, however, the lack of skill and intelligence in the operator. If we grant that a union which is practically perfect can be made,

then it seems to me plain that there may be many cases in which grafting would add to the vigor and longevity of a plant, and certainly we may be able to extend the range of certain varieties of fruit and ornamental trees if we can use the roots of one tree which are adapted to a certain kind of soil and graft upon it the top of another whose roots would not thrive in that soil. The grafting of European Grape-vines on American stock is a case in point. Our experience is that roots of *Rhododendron Ponticum* are never killed by heat or by cold here, and, therefore, they make an admirable stock, both for the varieties *R. Cawtawbiense* and the Ghent Azaleas in places where neither of these plants will thrive on their own roots. The best gardeners in England graft the Peach on Plum-stock where fruit is to be grown under glass.

But there is no need of multiplying instances to defend the practice of grafting as an indispensable one in many cases. I have said this much in the hope that other cultivators may give their thoughts and experience, so that some new ideas may be brought forth and suggestions made as to the directions in which the practice may be hopefully extended or in which it may be properly curtailed.

Flushing, L. I.

S. B. Parsons.

The Rose-beetle.

A PUZZLING problem to the horticulturists of southern New Jersey is, "What may be done with the rose-bug?" and the question may become of serious interest generally. This insect, *Macrodactylus subspinosus*, threatens to occupy as prominent a place in our agriculture as does the potato-beetle. It is even more formidable. We know how to deal with the potato-bug, but ingenuity is thus far baffled in devising means of contending against the rose-bug. For some years my own experiences with it have cost a thousand dollars a year, and I am as helpless against this pest as when I began trying to defend my plants from its ravages.

In this region, colonies of rose-bugs have existed in various localities for several years. I first saw a few of them in the corner of my vineyard in 1886. The next year I found there many more of them occupying an extended space. In 1888 they reappeared in multitudes. In 1889 they came in myriads, from the soil of my vineyard, where my colony hibernated, and also migrating to me in swarms, generally from the westward. At the same time this rose-bug irruption seemed prevalent over a wide expanse of territory. Seemingly, in their primary colonies, where we have known these insects for many years, they have been steadily increasing and have at last swarmed forth to "fresh fields and pastures new." There is reason to fear that this swarming may continue. It is a rule of life that, when supplied with food, population tends to increase and occupy new territory. The Colorado beetle staid in its western home until our extending agriculture offered it inducements and facilities for emigration to the east. When it could find food it started on its travels. It is here at home with us, and, while we grow food for it, the potato-bug naturally will enlarge its family and be our thriving guest. For a time there was hope that like some other epidemics this bug-affliction might pass away; but this hope is yearly disappointed. If *Macrodactylus subspinosus* thrives upon our agriculture as does *Doryphora decemlineata* there is work in store for our entomologists. As a foe to viticulture, the rose-bug is more dangerous than all our rots and mildews. Those who have suffered from slight attacks of this insect pest have no conception of what it may be. When they invaded my premises last summer, 1889, they devoured all the fruit on some 4,000 vines in spite of every effort to prevent them. I was not shorthanded, and for several weeks I waged constant war upon them, employing every means of destruction which could be suggested. With me the visitation of the bugs lasted a month, and when they were gone my grapes were gone. The grapes I harvested were from vines which they failed to visit.

The experiments I was making to test preventives of Grape-rot were chiefly a failure, because where the rose-bugs came they left no grapes to rot. Thus, in an isolated block of 450 vines devoted to certain special treatments, and which at the first treatment were full of blossoms, I did not find a cluster left when I went to spray them again. I have a number of vines of specially valued sorts, which I made special efforts to protect. Every morning for three weeks I visited them, before sunrise, and often through the day, knocking off the bugs and killing them on the ground. I thus killed daily hundreds of bugs on every vine. Often when I jarred a vine the ground beneath it would look yellow from their number. It is needless to say that no grape blossoms escaped on these vines.

I have a Sweet Gum tree which is particularly affected by the rose-bugs. At the height of their invasion this tree was occupied by millions of the insects, and at quite a distance from it they could be heard like the humming of a mighty swarm of bees. Looking upward one might see the bugs in the air, drifting like snowflakes from all quarters toward this tree. The ground around it, over the space of a half acre, was yellow with them.

I write these details to give the inexperienced some idea of what an overwhelming visitation may be made by *Macro-dactylus* when he sets forth to get a living. Of the fungus foes to the vine, we have (thanks to the French discovery of the uses of the copper sulphate solutions) henceforth but little to fear. I now am confident of ability to control grape-mildew and grape-rot, but before the rose-bug I am powerless. I have a large vineyard, but if they come next year as they did last summer I have serious doubt of harvesting any grapes.

I have found one mercurial drug which destroys the insect pretty promptly, but it is dangerous to the operator and to the plant. I would hesitate to risk its use, and will not recommend it. Besides, of what avail is it to kill the advancing hordes of this hungry host which pours on in ever-increasing multitude? I think that our protection must be found in some chemical which will be offensive to and thus repel the insect. But I have not found this yet, though I have tried many. In 1887 I fancied that the spraying with copper sulphate solutions was repellant to the bug, and so I reported it. That year they promptly forsook the vines sprayed with Bordeaux mixture. This year they did not, or perhaps the constantly arriving bugs kept up the depredation on the vine. If each took but a mouthful and passed on, it was enough to devour every blossom.

A sure and safe way to kill the insect is to jar them from the plant and kill them on the ground with a paddle. This may be done early in the morning, when the insects seem torpid. After nine o'clock they fly when disturbed, and thus escape damage. Last summer I found a way to overcome this difficulty, and shall resort to it next year with a slight hope of better success. Of good insect powder (pyrethrum or buhach) make a solution, one ounce of the powder to two gallons of water. First wet the powder to a paste before mixing with all the water, and spray the vines with this mixture. The bugs will be paralyzed, fall to the ground and lie helpless for a time. Have men to pass along both sides of the trellis to jar the vines and kill the bugs. The insect powder does not kill them; it only stupefies, and they will finally recover and fly away. But meanwhile they will be still for a while at any time of the day, and thus we may war upon them more destructively, and by constant attention, almost day and night during the rose-bug epidemic, a portion of the fruit, on a limited number of vines, may be saved. The invasion usually lasts about four weeks. As our territory becomes more densely cultivated the parasitic insects and fungi will spread as do infectious diseases through dense populations. In time our viticulture must be greatly modified. To manage large plantations of vines in this way will be impossible, and grape-growers will be limited to as many as they can fully protect.

Vineland, N. J.

A. W. Pearson.

[Colonel Pearson's statement of the problem is accurate, and, from all evidence, the account of injury done is not at all overdrawn. The insect passes the larval state in the ground, feeding on roots of grasses, etc., and is not injurious in that stage. It then resembles a small white grub. In spring the beetles emerge and pair freely. They are especially fond of flowers, and not only those of the Grape, but almost all others attract them, and are injured. The habits of the larva render it next to impossible to reach the insects in that stage, and the imagoes appear in such numbers that, even if all were poisoned one day by a single mouthful, that single mouthful would mean the crop of grapes. A modification of Colonel Pearson's remedy seems the best thing yet proposed. On a light frame of convenient size stretch a piece of muslin so that it shall sag in the middle. Early in the day send a man each side of the trellis with such a frame and jar the beetles from the vines. At intervals dump the collected beetles into a pail of water with a thick scum of kerosene floating on it. Not only from Grapes but from all other favored plants, should the beetles be collected. This is essentially a case where co-operation is necessary, and all interested should unite

and systematically fight these pests, not for one season alone, but year after year, so as to keep them down to harmless limits.

In Germany thousands of bushels of cockchafers are annually collected, and thus only are the trees in many localities saved from complete defoliation. The Government there pays a small bounty, and collecting is compulsory. A common interest here should unite the farmers and lead them to do what there is no legislation to compel. Entomologists may yet find some weak point in the existence of this species; but for the present the suggestions above are all that can be made.—Ed.]

Perennials from Seed.—I.

THERE seems to be some doubt among amateurs as to the feasibility of raising hardy plants from seed, and, judging from advice given in some horticultural papers, it would appear that this, the most natural method of increasing one's stock of perennials, was but indifferently understood. When it is taken into consideration that seed is the medium which Nature has provided, and by means of which nearly all plants naturally spread and perpetuate their species, it only remains to take into consideration the surroundings in which the plants are found, such as climate and position, to enable even the uninitiated to succeed in raising these plants from seed. To American cultivators the one great difficulty encountered at the outset is the means of obtaining good and fresh seed of plants of this description, as there does not appear to be any one yet who has taken up this branch of business and made a specialty of it; for, as a rule, none but the commoner kinds are catalogued, and these are easily and cheaply purchased, while the more rare and expensive kinds are no more difficult to raise from seed, and a good, thrifty plant raised in this way is far more likely to become established than a miffy or minute imported plant. Nothing is more certain, however, than that when the demand comes, the supply will be equal to it.

During the past two months we have sowed over 400 kinds of seed, many of them being seeds of plants which cannot be obtained in any other way. Of those sown about one-fourth have yet to germinate, and this is just about the percentage of perennials which do not come as easily from seed as annuals. With these even it is only a question of time and careful attention in the matter of watering in some cases, while with such as are indigenous to alpine regions, judicious freezing is needed to bring about germination with the advent of spring sunshine. Of those plants whose seeds are usually long in germination, a large number are included among the *Ranunculaceæ*, such as *Trollius*, most of the awned *Anemones* and *Clematis*. In the same list belong species of *Iris*, which have round seeds, *Dictamnus*, *Alströmerias*, most *Liliaceous* plants, and some of the *Fumariaceæ*, as *Corydalis* and *Dicentra*. This rule, covering certain families, is by no means a hard and fast one, as for instance, we sowed seed of the pretty Algerian *Ranunculus bullatus*, and it germinated in a week, while the seeds of *R. Lyallii*, probably the finest of the genus, which we have recently received from New Zealand, may require two years before they appear from the time of sowing. At least this time was required in the only instance of which one can find record where these plants were raised from seed. This is an exceptional case, of course. We name the above kinds as extreme cases, so that there need be no disappointment at delay. The best time to sow seeds of perennials, when it is intended to do so on a large scale, and where a good, light structure and fire heat are at disposal, is, without doubt, as soon as good, fresh seed can be purchased from the growers, or, in other words, any time during the winter or early spring months.

There is a two-fold advantage in sowing as early as possible, in that it not only enables one to devote the necessary attention to the young seedling plants at the proper time and when out-door work is at a standstill, but also that the plants may be strongly established in pots when the time arrives for transferring these to their permanent quarters in the open ground, where many of them will flower the first year, or within twelve months from the time of sowing. We are aware that it is usually thought best to sow seed of all kinds in spring, when increased light and sunshine may be relied on to accelerate growth, and this is so when one has not control over the conditions necessary to ensure germination and a subsequent continuation of growth, as in a well-heated house. Should a hot-bed or cold frame be the only facilities

at command, the success need not necessarily be less, but sowing must be deferred until the departure of frost. On sowing in the open ground we cannot speak favorably, owing to the trying influence of long continued drought and heavy thunder-storms. O.

Passaic, N. J.

Cattleya Dowiana and its Varieties.

THIS superb *Cattleya* is now becoming pretty common in collections, thanks to recent importations; and, as is usual in such cases, it already shows traces of a certain amount of variability in the color of the flowers. It is certainly one of the showiest and most distinct of summer-flowering *Cattleyas*, and will doubtless become still more universally cultivated in the future. The rich crimson-purple lip, exquisitely penciled with radiating golden lines, forms a brilliant contrast with the clear yellow sepals and petals, and imparts a charm to the flower which could scarcely be excelled under any circumstances. It is somewhat curious that so beautiful a species should have remained unknown in gardens so long after its discovery. It was originally detected by Warszewicz, about 1850, in Costa Rica, and both living plants and dried specimens were sent to Messrs. Low & Co., of Clapton. The plants never reached their destination, hence it was that for some years afterward doubts were entertained of the existence of so superb a *Cattleya* as that which the letters of the traveler described. About fifteen years afterward, however, it was re-discovered by Mr. Arce, a native naturalist, who was engaged in collecting natural history objects in Costa Rica for Mr. G. Ure Skinner. Plants were sent to England through Captain Dow (after whom the species was named), and one of them flowered in the establishment of Messrs. James Veitch & Sons, of Chelsea, in the autumn of 1865. It is said to be restricted to a small area on the slopes of the great central mountain range facing the Pacific Ocean, and to exist only in very limited numbers. This is the old typical form, and still rare in gardens; indeed it is said to be more difficult to cultivate than the varieties.

It is highly curious that a form of the same species should grow in New Granada, over 600 miles distant from the native home of the typical *C. Dowiana*. It is the variety *aurea*, and was discovered by Gustav Wallis in 1868, near Frontino, in the state of Antioquia. Rœzl places its habitat near the river Cauca, at a considerable distance above its confluence with the Magdalena. It chiefly differs from the typical form in having the markings on the lip more copious and irregularly distributed over the surface. It is the discovery of this variety which has chiefly helped the plant to become so common in gardens, as the old Costa Rican form is still comparatively rare. It is also said to be more easily cultivated, and certainly seems to be more variable. The variation chiefly resolves itself into a paler or deeper shade of yellow in the sepals and petals, and the relative preponderance of the crimson or golden-yellow markings on the lip. But slight as this may appear on paper, it amounts to a great deal when a number of plants are seen growing together. In some species it would mean the difference between a good and a bad form, though in so grand a species even the worst forms are very beautiful.

The variety *chrysotoxa*, originally called *Cattleya chrysotoxa*, and recently figured at t. 80 of the *Reichenbachia*, is best distinguished by having a large, dark crimson-purple, triangular blotch in front of the lip, which gradually passes into a narrow border of the same color behind, thus leaving a large and very characteristic golden-yellow space on each side of the throat. Other varieties do not appear to have received distinctive names, and perhaps it would be difficult to find constant marks of difference, for they pass so gradually the one into the other that the differences observed may be said to be chiefly that of mere individuals of the same species. The opposite extreme to the one just mentioned is when the crimson color preponderates and the yellow is confined to the radiating nerves. Forms possessing this peculiarity are exceptionally gorgeous, especially when the sepals and petals are of a deeper shade than usual.

The New Granadian form of *Cattleya Dowiana* is known to grow with *Cattleya labiata Warszewiczii* or *C. gigas*, as it is often called, and the result is that several well-marked natural hybrids have appeared in collections in which the characters of the two are unmistakably blended. *Cattleya Hardyana* was the first of these which appeared, and a splendid figure may be seen at t. 231 of the "Orchid Album." *C. Massaiana*, figured at t. 362 of the same work, is equally beautiful, though perhaps less distinct than could be wished, and better called a variety of *C. Hardyana*. In these the characters of *C. gigas* preponderate, especially in the color of the sepals and petals; but in

other specimens, not yet figured, and probably resulting from the reverse cross, exactly the opposite takes place, for the sepals are but lightly marbled with pale rose, while the petals have the ground color of this shade, but the whole copiously veined with light yellow in just the same way as the lip. The effect of this is very curious, though the colors are not as brilliant as in the other forms. Several very beautiful artificial hybrids have also *Cattleya Dowiana* for one parent, and thus we see how important a place it fills in our collections.

Horticultural Notes From California.

To the Editor of GARDEN AND FOREST:

At this time, January 7th, the San Francisco florists have no out-door Roses. After such a long-continued storm, the only dependence is on plants grown under glass. A few Daffodils and Lilacs are in the market—early flowers from sheltered gardens. The flowers of the Japanese Quince have begun to appear, masses of yellow Acacias are sold on the streets with flowers of *Magnolia grandiflora* from San Raphael, and violets were never more cheap and abundant.

The coming favorite here, among spring-flowering bulbs, is undoubtedly the Daffodil. None are better adapted to California soil and none are more popular. For ten years I have seen the interest in this flower increase, and thousands of bulbs are now being planted. The only Daffodil known here has been the common Yellow Trumpet, but last year collections of English varieties and of other species began to appear, and one occasionally sees a flower of *Narcissus Horsfieldi*, or of *N. praecox pallida*. Naturalized here, among the shrubbery and in hill-gardens, the Daffodil requires no more cultivation than our Eschscholtzias.

A vast amount of Rose-planting is going on in California, and the results will be charming in a few years, as good varieties are mainly used. Several nurserymen have estimated the yearly Rose-sales at 250,000, and of course a great many amateurs propagate plants by the hundred for their own gardens.

The importation of Japanese trees has become a large business here. Four or five firms engage in it. Mrs. Berger has brought over Camellias twelve feet high and in full bloom, and some wonderful collections of Chrysanthemums, Peonies and Lilies. I understand that a large part of the Japanese plants sold in this city are sent to the Atlantic states and the South, or even to Europe, and that few Californians are willing to pay for the choicest things that are imported. This agrees with what some of our older nurserymen have often told me, that the taste for fine plants is at present suffering an eclipse here: The actual number of choice conifers and rare deciduous trees and shrubs that were sold in this state twenty years ago was larger than it is now. The number of beautiful private grounds has not appreciably increased in the region around the Bay of San Francisco, since 1870. Cottage-gardens are more abundant; streets and lanes are more often planted with trees, but that reign of ornamental horticulture, which half a century ago was predicted as certain to come to California, appears little nearer now than a score of years ago. At present hardly a nurseryman in the state keeps the leading Pacific Coast conifers.

"I cannot sell Deodar Cedars, Araucarias, Umbrella Pines, or even our beautiful native Lawson's Cypress," said a prominent nurseryman to me lately.

The trouble appears to be that the enormous growth of the orchard interests, and the capital invested in them, have kept nurserymen and planters alike busy with the practical side of horticulture. Perhaps, after a while, the ornamental department of the nurseries will have a sudden development.

The great rainfalls, floods and heavy snows in the Sierras, have set people thinking about the forests. More than one of the daily newspapers have called public attention to the warning involved. If the snows are to be held back in the mountains, they urge, the trees must be saved. "On the preservation of the forests the prosperity of the greatest interests of the state depends," says the *Daily Bulletin*. It remains to be seen whether this interest can be directed into forms of efficient action.

Charles H. Shinn.

The Citizen's Rights in City Trees.

To the Editor of GARDEN AND FOREST:

Sir.—In your issue of December 18th, Professor Bailey, of Brown University, asks sympathy with his "growl" at the use of sidewalk-trees as telegraph-poles in Providence, R. I. I do not know what sympathy he has received, but I should like

to take the liberty of suggesting that he should not be content with growling if he really cares for the trees.

I presume that the trees in question belong to the city—that is, to the citizens of Providence, subject to the control of the city authorities for the benefit of the citizens. Should the trees happen to be on private property, and free from municipal control, the matter would be simpler. The guilty party is, presumably, a corporation, and even if its officers are deaf to the appeals of reason, they cannot be so to the commands of law. The use of the city's shade trees as telegraph-poles is so manifestly contrary to the interests of the citizens that if Professor Bailey consults a lawyer he may, perhaps, find that he is not without legal remedies after all. To make use of them, however, would require some money, the ultimate co-operation of the authorities, and a sufficient public opinion to sustain the movement.

The latter requisite, if obtained, would bring the others with it, and hence is the first to be secured. If no citizens' association to prevent municipal abuses already exists, Professor Bailey and his sympathizers would have to start the movement themselves. Providence is reputed to be a city of intelligence and wealth (although the only Rhode Island member of the American Forestry Association does happen to reside in Newport), but it is impossible that all the men and women care only for the profits of this telegraph company, and nothing for the trees. Let the tree-lovers organize, secure the co-operation of the local press if possible, appeal to all intelligent men and women (especially the latter), develop public opinion, raise funds for agitation and litigation, and then go before the authorities. If the company has such a "pull" on them that they will not order the wires off the trees, perhaps they may be legally compelled so to order, or the matter may be made a test at the next local election. I believe Rhode Island has adopted the Australian ballot, which facilitates independent nominations, and if so the tree-reformers can run their own men very easily. If Professor Bailey and his friends are too busy to do all this personally, let them get the students in botany to organize for the work. If the students have no enthusiasm for the trees, the lectures they have listened to have been worse than useless. Then there are the students of constitutional history, of political economy and of law. One good object lesson in the ins and outs of local politics, and the acquisition of corporate privileges would be worth months of reading and lectures.

But all this to save a few trees? Well, what did Professor Bailey's growl mean, if not that his rights and privileges had been attacked as well as the trees? Though in this, as in countless other things, that great indictment of popular government holds good, "What is every one's business is no one's business," are not the rights of the citizen always worth defending? Unless Professor Bailey is as ready, to the full extent of his power, to save the trees as the company is to injure them, I fear his growl will be fruitless.

Philadelphia.

Charles C. Binney.

Cor. Sec. American Forestry Association.

The Christmas Rose.

To the Editor of GARDEN AND FOREST:

Sir.—For more than thirty years I have had a Christmas Rose, *Helleborus niger*, in my flower-border, and it always gives me blossoms for Christmas day. This year, owing to the mild season, it blossomed earlier than usual, about the 1st of November, and it is still flowering on the fifteenth of January.

The merits of the plant are: (1) That it gives flowers when other plants are out of bloom; (2) the cut flowers keep fresh in water for nearly a week; (3) it needs no particular care or cultivation. My plant has been in the same place thirty or more years. If we have a very cold night or day I cover it with a box, but I give it no protection at other times.

I write this with the impression that the Christmas Rose is but sparingly cultivated about Boston, and with the hope that others in this region may be led to make trial of a plant which will give them great satisfaction.

Brookline, Mass.

T. E. Francis.

The Mild Winter.

To the Editor of GARDEN AND FOREST:

Sir.—It may be worth while to give a list of plants in bloom in the open ground and in mid-January at Raleigh: Japan Quince, Spiræas of several sorts, Tea and China Roses, Hyacinths, Tulips, Narcissus in variety, Kämpfer's Iris, Petunias, Violets and Pansies, *Bellis perennis*, perennial Candytuft,

Verbenas, Scarlet Geraniums, showing buds on new growth made since November, Strawberries in bloom and fruit, Sweet Alyssum, Drummond's Philox, China Pinks and Carnations, Wallflowers, *Jasminum nudiflorum*, and perhaps other things I have not noticed. Madeira Vines have grown three feet high, and *Lilium candidum* flower-stalks a foot high. A Maréchal Niel Rose clambering over my front porch has at least 500 buds on it, and a large Banksia Rose on a trellis near by is forming buds. Strange to say, none of our Peach-trees have bloomed, but in Anson County, on the South Carolina line, Peaches are as large as nutmegs, and winter Oats and Rye are in full head. Many Peas and early Potatoes have been planted, and change now to freezing weather would be disastrous indeed; yet we can hardly hope to escape altogether.

Agricultural College, Raleigh, N. C.

W. F. Massey.

Periodical Literature.

THE following account of the Spath nursery at Rixdorf, near Berlin, is condensed from a recent issue of the *Gartenflora*. This nursery, which is one of the largest and best equipped in Europe, is remarkable for the new plants it has introduced, especially those from Persia and central Asia. It covers about 600 acres, and is divided into nine departments devoted to different classes of plants, each department being under the control of a head-gardener who shares in the profits of his department. Between 300 and 350 workmen are employed, many of whom have been in the nursery since its establishment, a quarter of a century ago. Their devotion and skill are shown in the fact that, in spite of its great extent, there is not a nursery in the world so absolutely free from weeds. The same care and intelligence are shown in the offices, where an exact and separate record is kept of each department, embracing not only the moneys expended and received, but the plantations made, the development of the plants, and every other detail which can serve to throw light upon the business. It is said that 6,000 species and varieties of trees and shrubs are cultivated, exclusive of about 1,000 kinds of Roses and 600 varieties of fruits; but this estimate is probably an exaggerated one. It is interesting to know that nine of the ten plants sent out from the nursery for the first time this year had been obtained from the Arnold Arboretum. A large number of new varieties have originated in the Spath nursery since its establishment, and among them are several novel forms of American trees, such as *Tilia Americana Moltkei*, and a silver leaved Occidental Plane. Spath's golden-leaved Dogwood is now well known as one of the best plants of its class in cultivation; and several of the best forms of the common garden Lilac originated at Rixdorf.

The following figures give some idea of the extent of the business: Between 500,000 and 600,000 plants are grafted in the course of the year. About 4,000,000 seedlings are grown and 15,000,000 cuttings are struck, besides 75,000 cuttings of conifers; 50,000 conifers are grafted, too, annually. Nearly 2,500,000 ornamental plants are available for the annual sales, beside a quarter of a million standard fruit trees.

All the roads that lead out from the city toward the nursery are planted with interesting avenue-trees, often of uncommon varieties, as, for example, *Populus Bolleana*, *Pterocarya Caucasica*, and Paul's new Scarlet Double Thorn.

What may be called the Dendrological Museum or Arboretum proper is, perhaps, the most attractive part of the nursery to the non-commercial visitor. It is, of course, too small to allow the plants room for free development, but the arrangement in groups, by families, allows ready and satisfactory comparison of the different species and varieties in their young state and greatly facilitates the choice of plants grown in the nursery. The specimens in this special collection are plainly and generally accurately labeled with porcelain labels on which the names are printed in clear, bold-faced letters. There is a collection of standard Apples, and of Pears worked both on Pear and Quince-stock, and one of the long alleys through the nursery is bordered with selected specimens of ornamental trees, containing many with colored foliage.

The soil of the nursery is well suited to the cultivation of Hyacinths, Tulips and Lilies, as the whole area east of Berlin is composed of sand, with a subsoil similar to the famous bulb-growing districts of Holland. A large area is devoted to the cultivation of Lilies-of-the-Valley, principally for the American market. Lilies of many sorts grow in the nursery more vigorously and continuously than in almost any other part of Europe.

Herr Spath comes of a family of gardeners, his ancestors having been well known in the Berlin trade during the last two

centuries. As long ago as 1758 they established themselves on Copinger Strasse, and here there are still the town offices and the city residence of the present proprietor. It is not surprising that, as it is now developed and organized, the Spath nursery should attract many visitors from foreign lands as well as from all parts of Germany, which has no more instructive dendrological collection. It may interest American travelers to know that visitors are always welcomed by Herr Spath, and that the nursery may be reached from Berlin either by carriage or in a steamer to Neuer Krug or Borussia, or by the tramway of the Ring-bahn to Rixdorf, whence an easy half-hour's walk leads to the establishment.

Notes.

Newtown Peppins were sold in London on Holiday week for \$19.60 a barrel.

The well-known Frangipanni essence is made from different species of *Plumeria* (a genus belonging to the Dog-bane family), which grow in the West Indies and certain parts of South America, and especially from *P. rubra*, a native of Jamaica.

The ninth annual meeting of the American Horticultural Society will be held in Austin, Texas, beginning on February 17th, and continuing for five days. An admirable programme has been arranged, and the meeting promises to be one of special interest.

In the greenhouses of Messrs. C. Strauss & Company at Washington, five acres of glass cover 80,000 Rose-bushes, of which 20,000 are of the Wootton variety. All are grown exclusively for cut flowers, and during the season from 10,000 to 25,000 buds are cut each day.

It appears from a note in a recent issue of the *Revue Horticole* that in the three months of July, August and September of last year no less than 1,192 cases, containing 700,000 bulbs were exported from Yokohama to the United States and Europe. A large proportion of these bulbs were, no doubt, *Lilium auratum*, which the Japanese grow as a field crop.

Some days before the close of the year the amount of rainfall for 1889 was announced to have been 58.68 inches, a quantity in excess by 3.34 inches of that recorded for any year since 1871, when the Signal Service Bureau first kept the record. The largest monthly amount fell in November, 9.82 inches; but it is more unusual to find July next on the list, with 9.63 inches.

The way in which foreign plants become "weeds," under new and favorable conditions, is illustrated by the recent case of *Melilotus alba* in our western states. Introduced a few years ago as a garden-plant, it has spread so rapidly in the rich bottom lands along the Missouri River that it is fast driving out the Sunflower and other native weeds. It is commonly called the "Bokhara Clover."

At a large dinner recently given in Washington, a space in the centre of the table nearly forty feet long and eight feet wide was sunk so that the 600 potted Ferns with which it was filled rose but a short distance above the table-cloth. Innumerable little electric lamps were scattered under the Fern fronds; no other lights were used in the room, and the effect is described as particularly charming.

Although the first Chrysanthemum exhibition held in Europe was held in Vienna in 1831, so little attention had recently been bestowed upon the plant in that city that the show organized last autumn was described as a "novelty." About a thousand plants were shown in 1831, belonging to fifty-five different kinds; this year the same number of plants represented 400 varieties. The massing of the plants in a large glass rotunda was described as very effective, but few individuals of great excellence were noted.

A correspondent of the New York *Sun* writes from South Carolina that a new value has been discovered in *Hibiscus esculentus*, the plant which furnishes the vegetable called okra or gumbo. Its stem furnishes a fibre which, like those of Ramie and Jute, can be woven into textile fabrics. Moreover, while in the other cases the fibrous and the woody elements are mixed together in the stem and have to be separated by hand, in *Hibiscus* the fibres form a central core surrounded

by the wood. They may, therefore, be separated by machinery and, being long and extremely strong, will furnish an excellent fabric at very small cost.

So many reminders of the mild winter have been received at this office that we have no space to notice all of them. Very interesting was a photograph of a group of Christmas Roses which came from Cazenovia, New York, to testify how beautiful these flowers can be in mid-winter. We have received branches of many shrubs with fully-expanded flowers, and in a collection of this sort from the Meehan Nurseries at Germantown, together with many which we have heretofore noticed, were sprays of the Cornelian Cherry with the yellow stamens showing through the opening buds, and the Tartarian Honeysuckle with buds just opening.

The November number of *Macmillan's Magazine* contained an article by Mrs. Lecky on the "Gardens of Pompeii," which may be of interest to our readers as drawing at greater length upon the authorities quoted in the description of Roman gardens that was published not long ago in our "History of the Art of Gardening." The influence of the East on ancient European gardening is especially emphasized, and it is asserted on good authority that most of the gardeners of the Romans were Orientals. "At the very time when Roman power and luxury were in the ascendant, Italy was overrun with Semitic slaves. . . . Their gentleness and patience, their peaceful, laborious tastes, while rendering them unfit to be soldiers and gladiators, eminently qualified them for domestic service, and especially for the care required in tending plants."

The grass known as "Lalang" (*Imperata cylindrica*) gives the foresters of the Malay Peninsula more trouble than our own prairie grasses give the tree planters of the west. This Lalang is injurious by reason of its inflammability and because it prevents any cultivation of the land covered by it, except at great expense. Wherever land is allowed to run to waste it is soon covered with this grass except where the soil is wet, or sandy, or shaded by trees. The annual report of the Conservator of Forests at Singapore refers at great length to this plant, stating that it can be exterminated by chemicals, but these are expensive and have an injurious effect upon the trees planted in forest upon the land afterward. When trees are large enough to throw a shade the Lalang quickly disappears, and it cannot penetrate into forest glades if but a few trees bar its progress. The gradual planting of bushes and shade trees is recommended as the surest remedy for this grass pest.

The death of Peter Henderson removes a conspicuous figure from American horticulture. At the great establishment on Jersey City Heights, which he founded, the plants raised and sold every year exceeded in number those produced at any nursery in the world. His business as a seedsman was among the most extensive in the country. He was the author of many popular books, one of them, "Gardening for Profit," having attained a circulation of 150,000 copies. Every year, 200,000 of his illustrated catalogues were sent throughout the length and breadth of the country. He was a frequent contributor to many journals devoted to agriculture and horticulture, and a prominent place was always accorded to him at the meetings of the Association of American Florists, and of kindred societies, as well as in the business councils of his associates in the trade. Altogether he was more widely and familiarly known than any other man in connection with the horticulture of the country. And few men have exerted so marked an influence in his chosen field of activity. To him more than to any other one are we indebted for many improved processes in the production and distribution of plants. He not only aided in this direction by his writings but he exemplified his counsel in action, and a visit to his establishment was an object-lesson to all who wished to learn how horticultural practice could be made more cheap, simple and effective. Every square of glass and every foot of ground was always occupied to the full limit of its productive capacity, and every man was accomplishing all that was possible by trained skill and thorough organization. Mr. Henderson's alertness, enterprise and success as a business man was known to all the world, but only to those who were admitted to a closer intimacy was the genuine worth of his character fully revealed. His integrity was beyond any shadow of suspicion, his public spirit was universally recognized, his robust manliness and force were admired by all who came in contact with him, but the considerate kindness of his disposition will bring more tender memories to many a man who has received from him prompt and generous assistance at precisely the time when sympathy and help were needed.

Legislation for the Adirondacks.

FOUR bills prepared by the New York Forest Commission have been introduced in the Legislature.

The first authorizes the purchase of lands located within such counties as include the Forest Preserve. This provides that the Forest Commission, with the approval and concurrence of the Commissioners of the Land Office, may purchase lands in these counties at a price not to exceed one dollar and fifty cents per acre, and that no purchase of lands shall be made in excess of previous appropriations for that purpose.

The second amends the law regarding the formation and regulation of railroad corporations, so that Section 25 shall read as follows :

The Commissioners of the Land Office shall have power to grant to any railroad company formed under this Act any land belonging to the people of this State which may be required for the purposes of their road, on such terms as may be agreed on by them; or such company may acquire title thereto by appraisal, as in the case of lands owned by individuals; and if any land belonging to a county or town is required by any company for the purposes of the road, the county or town officers having the charge of such land may grant such land to such company for such compensation as may be agreed upon. The land included in the State Reservation at Niagara, and the Concourse land on Coney Island, and such lands as are included in the Forest Preserve, and that now are or that hereafter may be placed in the care, custody and control of the State Forest Commission, are expressly exempted from the provisions of this Section.

The third provides for a change of venue by amending the Code of Civil Procedure in certain cases; and the fourth amends the Act establishing the Forest Commission, so that Section 20 of Chapter 283 shall read as follows :

Every supervisor of a town in this State, excepting within the counties mentioned in Section 7 of this Act, shall be *ex officio* fire-warden therein. But in towns particularly exposed to damages from forest-fires the supervisor may divide the same into two or more districts, bounded as far as may be by roads, streams of water, or dividing ridges of land or lot lines, and he may, in writing, appoint one resident citizen in each district as district fire-warden therein. A description of these districts, and the names of the district fire-wardens

thus appointed shall be recorded in the office of the Town Clerk. The supervisor may also cause a map of the fire districts of his town to be posted in some public place, with the names of the district fire-wardens appointed. The cost of such map, not exceeding five dollars, shall be made a town charge, and the services of the fire-wardens shall also be deemed a town charge, and shall not exceed the sum of two dollars per day for the time actually occupied in the performance of their duties as such fire-wardens. The services of the persons who may assist in extinguishing a forest-fire shall also be a town charge, and shall not exceed the sum of one dollar per day for each person employed; but all bills for such services must be approved by the fire-warden of the town in which the fire occurred, before payment shall be made. It shall be the duty of the Board of Auditors in each town to promptly examine, audit and allow all reasonable bills presented to them by fire-wardens for services and disbursements under this Act, and for the payment of persons assisting in extinguishing forest-fires. Within the counties mentioned in Section 7 of this Act, such persons shall be fire-wardens as may from time to time be appointed by the Forest Commission. The persons so appointed shall act during the pleasure and under the direction of the Forest Commission. Upon the discovery of a forest-fire, it shall be the duty of the fire-warden of the district, town or county to take such measures as may be necessary for its extinction. For this purpose he shall have authority to call upon any person in the territory in which he acts for assistance, and any person shall be liable to a fine of not less than five nor more than twenty dollars for refusing to act when so called upon.

The most important of these measures is the one providing for the purchase of lands for the forest preserve. If the State is to own any land at all, it should gradually acquire title to the tracts lying between the blocks of land now held by the state. It should make a beginning with a small appropriation, and while wisely caring for what is already in its possession, should purchase such lands as can be cheaply acquired, and which are so situated that their acquisition would lessen the danger from forest-fires, and render the guardianship of the state lands more convenient and effective. It is most desirable that all the people of New York should come to have a more vital sense of proprietorship and responsibility regarding the property of the state in the Adirondack region, and an appropriation for the purchase of additional land would doubtless tend to produce this effect. All observers of the mountain forest-regions of the state unite in testifying that whatever the disposition or wishes of a railroad company may be, the extension of the road through new portions of the wilderness is usually followed by the denudation and ruin of large tracts of valuable forest-land. As the timber becomes accessible it is cut off without regard for the future, and much of the land is burned over so that forest-conditions are permanently destroyed. To prevent the farther extension of railroads over state lands would save more of the forests which still remain on these lands than any other measure that can be devised.

The bill providing for a change of venue in suits for trespass on state lands is necessary to an effective administration of the laws. Such cases cannot always be fairly tried in the vicinage where the depredations were committed. The apprehension has been expressed that some provisions of the Fire Warden Act might induce public-spirited citizens to rally for the extinguishment of fires in such numbers as to place a serious burden upon taxpayers, but some risk must be taken to secure the maximum of efficiency. On the whole the proposed legislation seems wise, and the bills should command the support of the press and the people of the state.

One of the most interesting botanical results certainly, obtained by Dr. Henry during his residence in western China, is the establishment of the fact that the Tulip-tree is an inhabitant also of that country. That monotypic species occur in eastern America and in eastern Asia is no new fact, but the plants common to the two regions discovered up to this time have been unimportant herbs, and the Tulip-tree is the first instance recorded of a

tree found in them both; and a tree, in spite of the long period of its cycle of existence, would be expected, from its greater exposure to climatic changes, to undergo greater modifications than a smaller plant. The presence of the same tree in Asia and in America is remarkable, perhaps, but it is not remarkable that Tulip-trees should grow in these two remote regions. It would be remarkable if one was not found in Asia in view of the similarity of the two floras, and of the fact that Tulip-trees of many species were at one time in the world's history widely distributed over its surface. The chief significance at this time, therefore, of Dr. Henry's discovery is that the climatic conditions of eastern North America and central China are so nearly identical that the descendants of a common tertiary ancestor—one in America, the other in China—have not become sufficiently altered during all the centuries they have existed to furnish to the eye of the systematic botanist differences sufficiently marked to enable him to separate them specifically. But we will refer our readers to the following account of the Chinese Tulip-tree, contributed to the columns of the *Gardeners' Chronicle* by Mr. W. Botting Hemsley, the author of the exceedingly valuable catalogue of Chinese plants now being published in the *Journal of the Linnean Society*:

It is just thirty years ago that the late Dr. Asa Gray published his memorable essay on the close degree of relationship between the floras of Japan and eastern North America respectively, as compared with the relationships between the floras of eastern North America and Europe, and between those of western North America and eastern Asia. I allude now to the vegetation of the temperate zone as distinguished from that of the arctic zone, in which there is a greater continuity of land and a much more uniform flora. The results of Gray's investigations showed that a considerably higher percentage of allied species inhabit Japan and eastern North America than inhabit western North America and Japan, or Europe and Japan. The number of identical species known at that date to be native both of Europe and Japan was rather greater than the number of identical species in eastern North America and Japan, but these consisted largely of species ranging from western Europe to eastern Asia.

The late Professor Miquel sought to minimize the importance of Dr. Gray's deductions, on the ground that many of the assumed identical species were different; but, whichever way we view it, there is no disputing the fact of the existence of numerous genera in the floras of both eastern North America and eastern Asia (China and Japan) that are not represented in the present flora of Europe, though there is evidence that some of these genera, at least, formed part of the pre-glacial vegetation of Europe.

Since the appearance of Gray's essay the flora of Japan has been more exhaustively investigated, and the immense botanical collections made in central China by Dr. Augustine Henry and others have revealed the existence of many other connecting links between the temperate floras of eastern Asia and eastern North America.

Among these discoveries none is of greater interest than the Chinese Tulip-tree. Almost everybody in England who is fond of trees is familiar with the North American Tulip-tree, which has no counterpart in its curiously truncated leaves among the trees hardy in Britain. Indeed, this type of foliage is not very closely imitated in any other genus of plants throughout the world; most nearly, perhaps, in some species of *Passiflora*.

In 1875 Dr. Shearer sent leaves of a Tulip-tree from China to Kew, collected on the mountains near Kiukiang, in the province of Kiangsi, in about the latitude of Ningpo, but between five and six degrees westward. Mr. Le Marchant Moore published an account (*Journal of Botany*, 1875, p. 225) of Dr. Shearer's collection of Chinese plants in which these leaves were found, and we learn therefrom that Dr. Shearer regarded it as a native of the region where he collected it.

In 1878 Messrs. Veitch, of Chelsea, presented to the Kew Herbarium a collection of dried Chinese plants made for them by Mr. Maries. This collection contained one small specimen of the Chinese Tulip-tree. It is quite young, neither the leaves nor the flowers being fully developed. Mr. Maries collected it near Kiukiang, from a tree growing near a temple; and in a note accompanying the specimen, he states that it was a fine spreading tree with green flowers, but he regarded it as inferior to the American. With regard to the color of the flowers, that was probably due to their very young state, and

the same may be said concerning their small size. Still the material was insufficient to decide whether it was specifically different from the American, and I accordingly published it as a doubtful variety under the name of Chinese in the *Index Floræ Sinensis* (*Four. Linn. Soc.*, xxiii., p. 25).

Early in the present year Dr. Henry sent to Kew copious completely developed specimens, confirming the view that it is the same species as the American, and not distinguishable, even as a variety. Judging from the specimens, the Chinese Tulip-tree presents exactly the same kind of variation as the American; the foliage of young or vigorous trees being much larger and more deeply lobed. Dr. Henry collected specimens on the mountains both north and south of the River Yangtze, in the province of Hupeh. At Paokang he found it forming a spreading shrub, six feet high, at an elevation of 6,000 feet. At Chienshih he collected flowering specimens from a tree thirty feet high, and leaves from a young tree in the same locality are a foot across in either direction. It bears a Chinese name signifying goose-foot-leaved Catalpa. The localities where Dr. Henry collected the Tulip-tree are between 300 and 400 miles westward of Kiukiang, a region previously all but unknown, botanically, beyond the banks of the Yangtze River.

French Parterres.

THE Luxembourg palace, one of the finest and most famous buildings in Paris, was begun by Marie de Medici in 1615, her architect being Jacques de Brosse. A smaller palace, razed to make room for it, had been owned for a time by the Duke of Piney-Luxembourg, and hence the name of the existing building. For many years during the present century it contained the State collections of modern art; but these have been removed to a new museum in the gardens near by, and the palace is now the Senate House. Our present object, however, is not to describe the palace itself or the large and beautiful gardens which surround it, but simply to call attention to the method of planting shown in the foreground of our picture (see page 55).

We spoke not long ago (vol. ii., p. 590) of the bad taste displayed in many French parks where bright, formal flower-beds and isolated tropical plants are profusely scattered about, with no regard to the main lines of the design or to the general effect which these were intended to produce. But such mistakes, frequent though they are, should not be taken as representative of the current level of gardening-art in France. Especially where the design is itself formal or semi-formal in character, the most perfect good taste and a keen feeling for harmonies of line and color are constantly revealed; and strangely enough, it may seem, the treatment is then apt to be less strictly formal and mechanical than in the essays of other nations.

The chief features in many of the small parks of Paris, and in those parts of larger grounds where there is close contact with architectural forms, are straight narrow paths and rectangular grass-plots, kept free from all scattered plants or beds, but encircled by long beds planted with a great variety of hardy flowers and shrubs. Such are the small spaces which surround three sides of the Louvre at the end where it faces the church of St. Germain, and many parts of the gardens attached to the royal suburban palaces as well as to the Luxembourg. The chief point with regard to the arrangement of the flower-beds is that, while symmetrical, it is not formal, either as regards the selection and arrangement of the plants or the method of their cultivation. Shrubby perennials—standard Roses, dwarf and low Standard Althæas and Persian or Chinese Lilacs being the favorites—are set at regular intervals along the centre of the bed, its ends being commonly marked by rather taller specimens. Between these, conspicuous annuals are set, and then the bed is filled to its edge with a varied mass of more lowly-growing flowers. In August and September there might be noted among the taller annuals Dahlias of different heights, Gladioli, Cannas, Asters and Bush-Daisies; and, among the others, Geraniums, Tuberous Begonias, Lobelias and Lantanas, with Centaurea, Coreopsis and *Gaura Lindheimeri*. These last were not mingled heterogeneously as isolated specimens, and neither were they clipped and restrained to make formal patterns. A little clump of each was carefully placed with due regard to the habit and the color of its neighbors, and then the whole mass allowed to grow in free luxuriance. Particularly pretty effects were produced by mingling red with white Geraniums, or by contrasting the red ones with a clump of white Centaurea; and, again, by allowing a pale Heliotrope and a yellow Lantana to interlock their

sprays. The blue Lobelias were carefully distributed so that they did not offend the eye by contrast with inharmonious hues; and, in general, excellent use was made of all the white flowers to separate and relieve those of vivid colors. In certain other French towns the grass-plots sometimes showed a central bed of flowers or foliage-plants, while shrubs were set near their angles; but no such instances were noticed in Paris, and the effect is far better when the grass furnishes a perfectly quiet background for its brilliant border.

Of course the spring and early summer aspect of such a border is different from the one we have described; but it must be equally charming, especially as then most of the standard shrubs would be in bloom. From the artistic point of view these beds are infinitely better than the flat pattern border; they are less mechanical in themselves, and, so to say, furnish a distant view more effectively, and they give the chance to use a great variety of beautiful flowers instead of only a few sorts combined with showy foliage-plants. From the practical point of view their superiority is as manifest. The standards, of course, are permanent; there is much less cost for wintering the other material, and much less labor in its arrangement and its subsequent care. After the summer planting has been done no care, indeed, is needed but watering and the occasional clipping of a plant which has run out too far over the grass. No one could question the beauty of the system who saw it last summer where it was most extensively and beautifully used—in the new gardens which occupy the former site of the Tuileries and connect the courtyard of the Louvre with the old Tuileries garden. Here acres were laid out with straight walks, grass-plots and long flower-beds, the lines being sufficiently varied to prevent monotony; and even when a large flower-bed stood by itself at the intersection of paths, it was arranged in a manner similar to that shown in the borders. The free beauty of the many flowers was enchanting as one passed by the successive beds; and the effect of the whole was harmonious yet brilliant in the extreme, and admirably adapted to the neighborhood of the stately buildings. In this case, and, indeed, in most others, the beds are not protected by the railing which in the Luxembourg garden somewhat injures their effect, but are merely divided from the walk by a narrow strip of grass, or at times by two such strips with a line of gravel between them.

Such borders are called by the gardener "French parterres," but it will be a pity if their use is long limited to France. Of course they too would be inappropriate as features in a natural landscape-design, but we often employ designs of this sort when formal arrangements would be better; and in these cases the graceful and varied symmetry of the French parterre strikes the happy medium between over-freedom and over-rigidity. With the great number of hardy flowers and shrubs at our disposal it ought to be easy—if, indeed, we possess an equal feeling for color harmonies—to exceed even the beauty of recent Parisian essays.

Californian Palms.

THE most remarkable arboreal feature of the deserts of southern California is the Washingtonia. It is as pre-eminent in its arid home as the Sequoia is in the forests of the Sierra, which it further resembles in growing only in a limited area. Perhaps the comparison may be carried further, for as the "Big Trees" now living are but the lingering giants of a vanished forest, so it is probable that these Palms are the scattered descendants of a more abundant race that once occupied the borders of the arm of the Californian Gulf which filled formerly the bed of the desert they now inhabit. We find them further north and west, at Whitewater, at an altitude of 1,126 feet. Thence the desert, broadening into a wide valley, falls rapidly, till at Indio, only seven miles away, it is twenty feet below the sea level, and at Frink's Spring, twenty miles further east, it is 260 feet below. In this depression the lingering waters formed a salt lake so recently that the record of its slowly receding levels is still visible in the discolorations of the cliffs which in places once formed its shore. It is along the hills which border the bed of this extinct sea that the most extensive Palm-groves are found, while scattering trees mark the direction of the channel which once led to the gulf.

These considerations may explain the anomaly presented by this Palm of being the only arborescent species in the United States which grows at any great distance from the sea.* Its station at Whitewater is the northern limit of Palm growth on the western side of the American continent, more than a degree further south than is reached by the *Sabal Palmetto* on the eastern coast.

*In Lower California, where it is found, Washingtonia is also a littoral species.

The Southern Pacific Railway runs through the desert I have mentioned, and between Indio and Seven-Palms stations some large groves of Washingtonias can be seen at the bases of the hills, a few miles to the north. A surface overlaying water, brown with alkali, produces here strips of damp soil, whitened with saline incrustations, which coat even the stems of the salt grass (*Distichlis maritima*) which spreads a sod of dingy green, grateful amid the surrounding bareness. Here the Desert Palm finds a congenial soil, for it is an oasis plant, and requires moisture for its roots. Though the most accessible, these are not the most satisfactory groves to visit. The number of really fine specimens here is not great, and most are badly damaged by fire. Their open situation exposes them to the full force of the desert siroccos, so that they have a gaunt and worn look, as if the struggle for existence had been hard. A smaller but much finer group is to be found in a sheltered cañon of the San Jacinto Mountains, some ten miles south of Seven-Palms station. Following a short distance the slender stream of clear water that runs through the narrow bed of this cañon, a more open place is reached, floored with wet sand in which lie half buried great angular fragments of granite. Here are growing a hundred Palms, mostly in the sand, but a few on the steep hillsides. There are some noble trees here, and the whole grove has an aspect of thrift.

Dr. Parry tells us* that the Desert Palm was discovered by the botanists of the Mexican Boundary Survey, who supposed it to be the Palmetto of the Atlantic coast. However, no mention is made of it in the report, and its first appearance in botanical literature is in the Smithsonian Report for 1860, where Cooper refers it doubtfully to *Brahea dulcis*, Mart. Then Herr Wendland, the distinguished Palmographer of Hanover, placed it in *Prichardia*, as *P. filamentosa*. Later, erecting for it a new genus, he called it *Washingtonia filifera*, fittingly reviving for the generic name one formerly bestowed on the Sequoia, but which the law of priority did not permit that genus to stand. The change in the specific name was less happy, as the strict construction of the recent reformers of nomenclature will demand that it be changed to *filamentosa*. Somewhere it has also picked up the name of *Brahea filifera*, by which it is usually known in horticulture. Its common names in California are Desert Palm, Fan Palm, or sometimes San Diego Palm, from its growing wild, in the United States, only in that county, and not in San Bernardino, as is usually stated in botanical works.

Seventy-five feet is probably the greatest height reached by the Desert Palm. The top is crowned by a cluster of light green leaves, whose stout stems, deeply channeled and beset along the edges with hooked spines, are eight feet, or more, in length. The plaited blades are some four feet in diameter, gladiately cleft at the edges, which are abundantly furnished with long, thread-like filaments. The leaves gradually turn down with age, until at last, layer over layer, they surround the trunk with a dry thatch, which descends in a regular cone from the verdant crown to the ground. This makes an admirable natural protection to the trunk from the scorching heat and drying winds of the desert. Unfortunately most trees have been deprived of this mantle. Its inflammable material is easily kindled by an accidental fire, and is an almost irresistible temptation to the passing vandal; but the most destruction is attributed to the desert Indians, who are said to burn the dry leaves that they may more easily gather the fruit. That any plants survive this ordeal of flame is strong evidence of the vitality of the species. No endogen could live through such a martyrdom. But of all the Palms of a fruiting size growing in the Colorado Desert very few have escaped it. I remember seeing only one tree, and that not over twenty feet high, with its protecting thatch uninjured. Naturally it would persist certainly many years. On cultivated trees, where the dead leaves are kept cut off close to the trunk, their fibrous bosses adhere so long that not more than four feet at the base will be free from them in a twenty-year-old tree. The bark is then seen to be gray, with close transverse fissures. The wood is fibro-vascular, with a specific gravity of .51.

A mature tree produces in June three or four large panicles of small scorious flowers. The stout terete peduncle ascends from the axil of a leaf near the centre of the crown, and is of the length of the petioles, so that the ultimate divisions droop over the blades. Gradually the peduncle declines, till, in September or October, the ripe fruit hangs pendent over the mass of dead leaves. Each cluster produces some ten pounds of fruit, the size of a large pea, with a thin, sweetish pulp and a bony seed.

The Desert Palm was early planted at the old Spanish mis-

*San Francisco Bulletin, March, 1881.

sions, and some fine specimens still remain. One of the best is in the grounds of Mr. T. H. Ramirez, in Los Angeles, and is now fifty years old. A careful estimate of the height, made recently by the Rev. J. C. Nevin, is as follows: Height of living leaves, 14 feet; mass of dead leaves,* 10 feet; trunk, 34 feet; total height, 58 feet; circumference three feet from ground, 10 feet 10 $\frac{3}{4}$ inches.

The same tree was measured in 1880 by Dr. Engelmann, who estimated the height as substantially the same, and found the circumference to be only four inches less.

A tree growing on Second Street in San Bernardino, twenty-two years from the seed, measures: To the leaves, 22 feet; roof crown, 10 feet; total height, 32 feet; circumference three feet from ground, 9 feet 2 inches. This tree has produced flowers and fruit for the first time the present year. During the last few years many thousands of these Palms have been planted in southern California, which in time will become notable features in the landscape.

So far as is actually known, the Palm already described is the only one indigenous in California, or, indeed, anywhere in the United States west of the Atlantic and Gulf coast-regions. There are, however, some indications that other species may be waiting discovery. Two species of *Erythraea* are near our borders. *E. edulis*, Wats., inhabits the island of Guadalupe, off the coast of Lower California, while *E. armata*, Wats., comes within thirty miles of the boundary on the Mexican side, and may be found in some yet unexplored cañon on the American side.

Ten years ago Mr. W. G. Wright obtained from the desert Indians a few Palm-seed of two different kinds, which appear to belong to no known species. They were represented to have been procured in the neighboring desert, but the most zealous efforts failed to lead to the discovery of the trees. There is some reason to think that they may have been brought from Mexican territory.

Washingtonia robusta, described by Wendland in 1883, is also supposed to be Californian, but its origin and character are alike doubtful. It was founded on some young plants raised in a Dutch nursery, the seeds of which were supposed by the proposer of the species to have come from the "Valley of the Sacramento River, in California"—an obvious error. Again, "M. Roezel is said" (by E. André in the *Revue Horticole*) "to have gathered the fresh seed in Arizona." It is quite certain that no botanist is known to have seen an indigenous tree. Seed-collectors, however, are more fortunate, and are able to supply abundantly the market with *W. robusta* seed, which has no apparent difference from that of the common Desert Palm, except its higher price. The published characters of the proposed species show no important points of difference from the better known one, and, indeed, are hardly sufficient for more than a garden variety. May not the seed from which the original plants were raised have been gathered from a *W. filifera* having individual peculiarities that impressed upon its progeny the minor characteristics by which they seem to differ from the ordinary form? Greater variations are procured by seed selection by cultivators, and among plants growing wild, marked individual differences are not uncommon. At best, this species is a very obscure one, and it is to be hoped that more light may be thrown upon its true character.

San Bernardino, Cal.

New or Little Known Plants.

Kalanchoe carnea.

THIS South American plant,† of which a figure appears on page 53, although it has suffered, perhaps, like most horticultural novelties, from over-praise, seems really an important and valuable addition to winter-blooming plants.

Like the *Crassulas*, to which *Kalanchoe* is very closely related, *K. carnea* is a very easy plant to manage. The seeds sown in the early spring will produce plants which will flower at Christmas-time. The seedlings may be potted during the summer or may be planted in the open ground and lifted and potted at the appearance of frost. The temperature of a warm greenhouse, in which the plants should get the benefit of as much sun as possible, will bring them into flower by the middle of December, or

*All the dead leaves were cut away two years ago, and these have accumulated since.

† *Gardeners' Chronicle*, ser. 3, i., 211, f. 48, February 12th, 1887.

they may be retarded in a cooler temperature. The habit of this plant is fairly good, but it can be improved by pinching the end of the main stem early in the season, which will then throw up three or four flowering branches. *Kalanchoe carnea* flowers freely, and the flowers, which are pale pink, are so fragrant that a single cluster will perfume a whole house. Its blooming at a time of year when flowers are more scarce and more in demand than at any other season of the year makes it a desirable plant; and the fact that it can be treated as an annual or can be propagated from small cuttings adds to its value; as the plants can be thrown away as soon as they are out of flower—an advantage which will be appreciated by persons with small greenhouses in which space cannot well be spared for plants that have passed their productive state early in the winter.

Kalanchoe carnea is so easily raised and flowers so freely that it is suggested that it may prove one of the best flowering plants for cultivation in rooms which has been introduced for some time.

Foreign Correspondence.

The Gardens at Burford Lodge.

PROBABLY some of your readers who are interested in Orchids will like to hear something of a garden which has become famous wherever Orchids are grown.

Among amateur Orchid-growers in England, Sir Trevor Lawrence, President of the Royal Horticultural Society, has long been the acknowledged prince. He commenced about fifteen years ago to collect and cultivate Orchids in his delightfully situated garden under the lee of Box Hill, Dorking, in the county of Surrey, twenty miles from London Bridge. About five years later it was acknowledged that no collection in England possessed as much interest or testified to as much cultural skill as this; the health and cleanliness of the plants, the orderliness and convenience of the houses being such as were scarcely ever met with elsewhere. This may be said of Sir Trevor's garden to-day. There are and have been collections of Orchids almost if not quite as rich in number and rarity of species, but they have not lasted long, and the only English collection which may be said to rival Sir Trevor's at the present time is that of Baron Schröder, at Egham, near Windsor. The marked difference between the two is that while the Burford Lodge collection contains almost every Orchid that is popular and beautiful it also admits many plants which have only a botanical interest. Sir Joseph Hooker recognized the exceptional services of Sir Trevor to horticulture by dedicating to him in 1886 the hundredth volume of the *Botanical Magazine*, and he associated with Sir Trevor's name "that of the distinguished lady from whom you directly inherit your love of plants and passion for gardening, the late Mrs. Lawrence, of Ealing Park, whose liberality and whose rich and beautiful conservatories were well set forth by my predecessor in the dedication to her of the sixty-eighth volume, published in 1842, of this work, and whose kindness to myself when a very young botanist, I shall ever hold in grateful remembrance."

Ealing Park about fifty years ago was probably the richest and most beautiful in England. Orchids, hard-wooded plants, stove plants, hardy trees and shrubs were cultivated there most successfully, as was proved by the place they took in the great exhibitions which were then held by the Royal Horticultural Society. In a description of this once famous garden, written at that time, mention is made of four houses, sixty-five feet by seventeen feet, filled with New Holland plants, amongst them magnificent specimens, four or five feet through, of such plants as *Leschenaultia*, *Boronia*, *Gastrolobium*, *Pultenaea* and *Chorizema*. Another house, forty feet by sixteen feet, contained nothing but *Ericas*, many of them large specimens of species which are not now known in English gardens. Reared in the midst of such surroundings, Sir Trevor could hardly help acquiring a great love for plants and taste for horticulture. When he succeeded Lord Aberdare as President of the Royal Horticultural Society it was rapidly sinking into ruin, and it had ceased to represent and lead English horticulture. Thanks, however, to the new departure decided upon soon after Sir Trevor's election to the presidency of the Society, it has been restored to activity and usefulness, and the Society is now rapidly gaining the respect and support of every one interested in horticulture.

Fig. 14.—*Kalanchoe carnea*.—See page 52.

It is the boast of Sir Trevor Lawrence that he is his own gardener. He does not, however, deny to his men the credit due to them for the successes achieved in his garden, and amongst them to one who stood head and shoulders above all Orchid-growers of his time, the late Mr. Spyers. Mr. Spyers was a gardener by instinct, as much as by training, and we are indebted to his extraordinary skill in arriving at the treatment best suited to many plants which had baffled others, or of which cultivators were in ignorance, for many Orchids which

are now grown with ease. Mr. Spyers died suddenly about five years ago, when still a young man. A garden rich in plants and perfectly managed, where some half dozen young men are employed amongst the Orchids, must effect a considerable amount of good in horticulture by training men in the best methods of cultivation. In this way a few good, well managed gardens are of immense benefit to horticulture generally.

The garden at Burford Lodge is what would be called small. It occupies about twenty acres, a large proportion of which is covered with grass and plantations. These latter are filled with Ferns, Daffodils, Primroses, Bluebells, etc., through which moss-grown paths meander naturally, and are roughly defined by patches of Ground Ivy. The houses number twelve, none of them being large. In construction they are as light as possible, the wood-work painted white inside and out, being only strong enough to carry the broad panes of glass. In winter it almost seems as if there were more light in these houses than there is outside. The stages are covered with spar, and beneath them is planted *Selaginella*, *Tradescantia*, etc. There is absolutely no attempt at ornamentation. The houses are built solely for the plants, and are designed by Sir Trevor himself.

The collection of Orchids comprises almost every species and variety of any horticultural interest, and a great many which are termed "botanical Orchids." If there is a good and rare plant in the market it is almost certain to be secured for Burford Lodge unless it be already there. Sir Trevor is a liberal buyer. Any plant on which he has set his mind he gets, no matter what it costs. It used to be said that of every importation of Orchids into this country the best plants went to Sir Trevor's garden. At the public auction rooms, at the nurseries, wherever there are Orchids worth having, there Sir Trevor is a frequent visitor.

In his address at the Orchid Conference in 1885 Sir Trevor expressed the opinion that of the 5,000 species of Orchids known close upon 2,000 were in cultivation. "I can say," he said, "with regard to one particular genus, *Dendrobium*, that I have had in my own collection upward of 100 species under cultivation at the same time. There is another curious circumstance to be noted in connection with Orchids, and that is, that I do not see, in the case of most of them, that there is the least reason why they should ever die . . . unless they are killed by errors of cultivation." Many growers find that, in spite of the most careful treatment, a great many Orchids are difficult to keep in cultivation. Yet Sir Trevor's remarks on this point are to some extent confirmed by the contents of his collection, many of which have been in his possession almost a generation. *Cattleya*, *Dendrobium*, *Cypripedium*, *Cælogyne*, *Vanda*, *Odontoglossum*, *Oncidium* and *Masdevallia* are each represented by scores, in some cases hundreds of kinds, whilst such genera as *Epidendrum*, *Catasetum*, *Brassia*, and even *Pleurothallis*, are not omitted. Hybrids have been raised amongst *Dendrobiums*, *Cypripediums* and several other genera at Burford Lodge, the fine race of *Calanthe* produced here being a special feature of this garden at this time of year. Rare plants, such as *Grammatophyllum speciosum*, *G. Ellisii*, *Spathoglottis aurea* (Kimballiana), *Renanthera Storeyi*, *Lissochilus giganteus*, and others scarcely known elsewhere, are represented here by large, healthy specimens.

Although famous chiefly for orchidaceous plants, yet the other departments of Sir Trevor's garden are well managed, and contain many choice and rare plants in well grown examples. Probably there is no other garden of the same size in England where so many beautiful, rare and interesting plants are collected together and grown so successfully.

London.

Notes on Grafting.

THE influence of stocks upon the scions or buds grafted and budded upon them is a subject which is often discussed and which is as yet very imperfectly understood. General experience maintains the theory that the leaves, flowers and fruit, as well as the woody parts, of a grafted or budded plant are essentially the same as those on the plant from which the scions or buds were originally taken, and that the plantfood taken up by the roots of the stock imparts little or no influence of its own quality or character when transmitted to the cells, and through them, to the growing parts of the introduced graft or bud. On the other hand, the variations recorded by Darwin and others show that a mixture of qualities may take place, and the so-called "graft hybrids" are

exceptions which invite unlimited study and experiment with a promise of some interesting results.

Although the physiological reasons for these phenomena of growth are as yet so little understood, the visible results brought about by the practices of the horticulturist are often very striking and well marked.

Considered in its practical aspect it is surprising to find, after such a long period of usage, so few authoritative accounts indicating the full value of any stock for any special purpose. The French horticulturists seem, more than others, to have made advances in the practice of grafting and the study of its results, and some of their manuals and notices of the subject contain much valuable information for the amateur. Undoubtedly a great impetus has been given to the study by the practice, in recent years, of grafting the wine-producing grapes of France upon the roots of American species in order to check ravages by Phylloxera.

We know that when scions of some species are grafted upon stocks of an allied species, or sometimes even on a different plant of the same species, an increased vigor often results. Michaux states that the striped Maple (*Acer Pennsylvanicum*) when grafted on stock of the Sycamore Maple (*A. Pseudo-platanus*) increased to four times its natural size.

There is almost no limit to the possibilities of inter-grafting between plants of the same species; but how far grafting may be successfully and economically carried between different species or allied genera is a matter of which comparatively little is known. The practice of grafting the Pear upon stock of the Quince (*Pyrus Cydonia*) is one of the few cases where long usage has made the results familiar to all, and the difference between the Pear grafted upon Quince stock and a Pear grafted on seedling Pear-trees is well marked. Thus it has been found, as a rule, that successful grafting is fully as easy on Quince as on Pear-stock; that growth on the Quince-stock, though more vigorous the first year, becomes less vigorous in succeeding years than when grafted on Pear-stock; when grafted on Quince fruit may be produced in two or three years, while on Pear-stock it cannot be expected for at least five or six years. The fruit is usually finer, larger and relatively more abundant on Quince-stock, but the trees are dwarfed, and, as a rule, are short lived, while they become large and are comparatively long lived when grafted on Pear. It is also noticed that the graft on Quince increases in diameter much faster than the stock and that the joining of the stock and graft is never so perfect as it is when the Pear is grafted on Pear stock.

Other points have been noted, and although much depends upon climate, soil and other conditions, and still more upon the character of some varieties of the Pear, the foregoing observations may be taken as an example of what is desirable in the knowledge of the value, as stocks, of hundreds of our trees, shrubs and vines. To know what stock will produce the best, longest lived plants of a variety grafted upon it, and, at the same time, give the most satisfaction in the abundance and quality of the flower or fruit, is certainly of great importance to the horticulturist. It seems to be true that certain stocks have an influence in hastening or retarding the leafing, flowering and fruiting of some plants; and the hardiness of some rather tender species often appears to be increased by grafting upon hardy stocks, probably because the wood becomes ripener and better matured before winter frosts.

No regular series of experiments in grafting has as yet been attempted at the Arnold Arboretum; but Mr. Jackson Dawson, the propagator, has tried a great variety of stocks, and while, as was to have been expected, many of them have so far proved failures, others appear successful and worthy of notice.

The following notes made within a few weeks among the plants in the collections and nurseries are given, because they may be of interest to others working in the same direction. Among such young plants time alone will tell what the ultimate result and value will be.

One of the most interesting cases is that of five specimens of western Larch (*Larix occidentalis*), all growing near each other in the same soil and receiving the same treatment. Three of the specimens were produced from seed collected in Oregon and sown in November, 1881. Two of them are five feet and the other three and one-half feet in height, and all have stems three inches in circumference at one foot from the ground. The greatest spread of branches is three and one-half feet.

The other two plants were grafts taken from some of the above lot of seedlings in January, 1884, and grafted upon stock of a Japanese Larch (*L. leptolepis*).

These are now seven feet high, and have stems six inches in circumference at one foot from the ground. The greatest

spread of the branches is five and a half feet. The point of insertion of the graft is not apparent in either plant. The seedling plants lose their leaves a little earlier, and are much more straggling in habit than the grafted specimens. Until within a few years it was not considered practicable to graft the Hickory. Young seedling and grafted specimens of these trees grown under the same conditions, show, in some cases, a little advantage in favor of grafting. As yet the only stock used at the Arboretum has been *Hicoria ovata* (*Carya alba*). A variety of *Hicoria ovata* grafted in March, 1887, is now over two feet high, and of four seedlings planted beside it, the seed of which was planted in October, 1883, three specimens are two and one-half feet high and the fourth over one and one-half feet. The scion of the grafted plant was only three or four inches long when inserted in the stock. No marked difference in size or vigor has as yet appeared in seedling and grafted specimens of *Hicoria sulcata* (*Carya sulcata*) now six or seven years old. The Hickories offer a field for interesting experiments to determine which are the best stocks for grafting purposes.

Among the Oaks, the English Oak (*Quercus Robur*) is found to be the best for all purposes as a stock. The only plants measured for comparison were two plants, growing side by side, of the dwarf Georgia Oak (*Q. Georgiana*). One of these, grown from seed collected in Georgia in November, 1876, is four feet high, and the other, grafted on roots of young plants of *Q. Robur* in January, 1884, is now over seven feet in height. The stock in this case increases in diameter faster than the graft. The seedling plants have been occasionally partially killed in winter, while the grafted plants appear to sustain no injury.

Another interesting case is that of a south-western Ash (*Fraxinus anomala*), in which grafted specimens again show greater hardiness and faster growth over those not grafted. Of two healthy plants growing side by side under exactly the same conditions, the seedling plant is now four and a half feet high. The seed of this was collected in Utah and sown in 1874. The other plant is from a graft taken from the above lot of seed-grown plants and grafted on a seedling of the common White Ash (*F. Americana*) in February, 1882. It is now over nine feet high and appears vigorous and hardy, while the seedling plant has often been injured in winter. Other plants of these lots show the same proportionate rate of growth, vigor and hardiness. The various species of Amelanchier and Cotoneaster grow vigorously when grafted on the European Mountain Ash (*Pyrus aucuparia*), and the former appears to thrive fairly well on stock of English Hawthorn (*Crataegus Oxyacantha*), while the latter seems to do very poorly.

The Pear is commonly known to grow well on *Crataegus*, but, no doubt, a great difference would be found in the value of the various species of thorn for stock. Some varieties of Pear, budded upon strong roots of the native scarlet Haw (*C. coccinea*, var.), have been known to grow with extraordinary rapidity and to produce large crops of fruit within three or four years, but, in the cases which have come under my notice, the stems of the Pear-trees increased in size much faster than the stock, so that the disproportion became very great and the plants died while quite young.

The increased longevity and value of the Peach when grafted on Almond or Plum-stock is well known, and there is reason to believe that stocks of the different species of Plum would produce such varying results that they would be well worth testing comparatively.

The value and advantage of grafting many of our choice varieties of Roses is now generally conceded, but there are still differences of opinion as to the best stock for such purposes. The Dog Rose (*R. canina*) and the stock known as the Manetti are those in most common use. In recent years the Japanese *Rosa multiflora* of Thunberg has been employed to some extent as a stock, and, at the Arboretum, a Japanese species recently described by F. Crépin as *Rosa Watsoniana* has been used with satisfactory results. Its peculiar advantage as a stock over the old species in use and over *R. multiflora* (of which it may be a form) lies in the fact that the suckers and stray shoots from the stock may be at once detected by the slender, long, narrow leaves which are very different from those of all other Roses. Similarity of foliage often renders it troublesome to distinguish the graft of a Rose from the stock. *Rosa Watsoniana* appears to be less vigorous in habit of growth than the other kinds used for grafting purposes. The Japan Quince (*Pyrus Japonica*) grows poorly on the English Hawthorn, and has refused to adhere to Apple stock for any length of time. But the Chokeberry (*Pyrus arbutifolia*) thrives remarkably well on the European

Mountain Ash. The Hobble-bush (*Viburnum lantanoides*) has not always been found to take kindly to cultivation when transplanted from its native woods, and the advantage of grafting it on *V. dentatum* has already been referred to in a recent issue of GARDEN AND FOREST.

Arnold Arboretum.

Water Lilies for the Million.

COMPARATIVELY few lovers of flowers can indulge in the luxury of growing Water Lilies in an aquatic-house, and few can afford sufficient space in a greenhouse for such a tank as G. B. recommends in vol. iii., p. 20, of GARDEN AND FOREST. But these plants can be more cheaply grown; and I will give a few directions from my own experience, in the hope that many lovers of flowers will be induced to take up the culture of these beautiful exotics.

The Water Lilies of the tropics require heat to start them and to flower them successfully, the dormant bulbs starting at a temperature not below eighty degrees. Our summers are not enough to flower them successfully out-of-doors, and plants sufficiently advanced to place in the Lily-tank can be purchased in May and June at \$2.50 to \$10 each. This is the

sixty degrees, but the growth will not be so rapid. When the plants have made three or four leaves they may be potted singly into three-inch pots, using the same mixture of soil. At this stage they will require more room. Shallow tubs or other convenient vessels may be used to place the pots in, but no more than three inches of water should be over the tops of the pots, and they should be kept in the full light to prevent the leaves from being drawn. Where several plants are placed close together care must be taken when it becomes necessary to move them, or the leaves will get entangled. The water can be changed by simply adding more, and allowing it to run over. A good plan is to put an inch or two of sand in the bottom of the tubs to steady the pots, but the plants must not be allowed to make roots through into the sand.

As soon as the pots are full of roots they may be potted again into five-inch or six-inch pots, using good loam and well rotted manure. Three plants will be enough to place in tubs (kerosene barrels cut in two answer well). When the pots are full of roots they are fit to plant in their summer quarters. One plant will then be sufficient in a tub. Three can be planted if the tubs are to be sunk in a tank, but they will

The Garden Front of the Luxembourg Palace.—See page 50.

barrier to more general cultivation. But seed of several varieties of *Nymphaea* are now advertised by leading houses at the moderate price of fifty cents a packet, and if care in cultivation is given fifty per cent. will, in many cases, germinate. Seed may be sown from January to March in shallow pots or pans of sandy soil. Those who possess a greenhouse will find no difficulty in maintaining the required temperature. The pots of seed should be placed in a shallow vessel filled with water, and directly on the heating-pipes, and kept dark or shaded till the seed germinates. Then all the light possible should be given. Those who do not possess a greenhouse may find some means whereby seed can be raised. A frame of common boards, six inches deep for the sides and ends, and covering with sheets of glass, would do for this purpose, provided a kerosene lamp was used underneath to keep the required temperature. When the seedlings are large enough to handle prick them off into seed-pans, using good loam, leaf soil and well rotted manure, in equal parts, rubbed through a fine sieve. Place the pans in shallow tubs, covering with about an inch of water, and it will not be necessary to place again directly on the pipes, but keep them in a temperature of about seventy degrees. They will not die in a temperature of

be crowded and the flowers will be smaller. If the plants are to remain in the tubs through the season, and not sunk in a tank, more space must be left for water. Use the same soil as when potting into six-inch pots, and finish off with two inches of clean sand. The plants will flower well in these tubs if kept constantly filled with water, but if at all vigorous, they will push their leaves over the edges of the tubs out of the water, and the sun will scorch them and check their growth. It is much better to place the tubs in a tank. The tank in which I have flowered Water Lilies successfully has been simply a hole of the desired dimensions, dug in a convenient and sheltered spot, yet open to the sun and having the sides and bottom concreted and finished off with Portland cement. An eight-inch brick wall would be more substantial, and consequently better, but my method may be used at first, and the brick-work left till a season's experience suggests improvements.

A very convenient size for a tank is five feet six inches wide, inside measurement, and not more than two feet deep. The sides should slope if concrete is used and an edge of a single brick will prevent the rim from being broken. If on the lawn keep the edge of the tank three inches below the

ground level. This will allow a sod to be laid and the grass will cover the unsightly brick border. With a tank of these dimensions a garden-frame and sashes may be placed over it, and the tubs can be set in much earlier so that the sun's rays will warm the water several degrees and the season can be considerably advanced. The same protection can be given in the fall and Water Lilies may be had for Thanksgiving.

In such a tank I have grown in tubs *Nymphæa Zanzibarensis*, *N. Zanzibarensis azurea*, *N. Zanzibarensis rosea*, *N. alba candidissima*, *N. odorata rosea*, *N. dentata* and *N. Devoniensis*, and have cut flowers of the Zanzibarensis varieties ten and a quarter inches in diameter, with leaves which measured twenty-two inches in diameter. *N. Devoniensis* is a superb night-flowering variety, as is *N. dentata*.

N. alba candidissima is the queen of white Water Lilies, but is not fragrant. It is hardy, however, as is also *N. odorata rosea* and *Nelumbium speciosum*. The latter will not do well in a tub with the same culture as *Nymphæa*, but should be planted out in the Lily-pond or aquatic garden. All hardy Lilies should be planted in deeper water than is recommended for the Lily-tank, as they will not bear freezing. All varieties of *N. Zanzibarensis* and *N. odorata rosea* (the Cape Cod Pink Water Lily) have most delicately scented flowers and can be raised from seed.

No mention has been made of an overflow or draw-off in connection with the tank, for I have none. There is always a certain amount of evaporation going on, according to conditions of the atmosphere, and it is only necessary to keep filling the tank up with rain water or spring water. In emptying, I syphon with a length of hose having a fall of two feet in fifty. To keep the water clean and free from mosquito-larvæ, a few gold fish are useful and add immensely to the general appearance of the tank.

Perennials From Seed.—II.

THE compost which is found suitable for all kinds of perennial plants is a mixture of loam and well decomposed leaf mould, in equal quantities, with the addition of a shovelful of charcoal dust to the bushel of soil. Should the loam be of a clayey nature, a shovelful of sand should be added. The influence of the charcoal is purely mechanical, but the benefits derived from its use cannot be overestimated. Before using it, we often found that, during a period of dull weather, the young seedling plants damped off in quantities, causing serious loss and disappointment. The charcoal has obviated this, but it necessitates a more frequent use of the watering pot. Before using, the soil should be passed through a quarter-inch sieve and thoroughly mixed, keeping a sharp look out for worms, which make trouble in the seed-pan. The soil, when in fit condition for use should by no means be dry, but it should not be so wet that any portion of it adheres to the hands. We use shallow seed-pans of two sizes, the smaller being four inches wide and two deep; the larger, seven inches wide and two and a half deep. Pans are preferable to boxes, unless the latter be new, as in old wood there is always a tendency to fungoid growth. The pans should be filled with soil to within a fourth of an inch of the top, and this should be made moderately firm and smooth with the bottom of another pan. The seed may then be sown evenly and covered with soil sifted through a fine sieve made of wire mosquito-netting. The soil left in the sieve should be used in the bottom of the next pan as drainage. Care must be taken not to cover the seeds too deeply; if they are barely hidden the covering will suffice. Many people advocate sowing small seeds without any covering. This necessitates shading from the sun, and if the seed be not quick to germinate, a mossy growth often covers the surface, through which it is difficult for small seeds to penetrate. Should this growth appear on the surface of the soil it may be smothered by sprinkling sand on it. When the seeds are sown the soil that covers them should on no account be pressed, as this renders germination very difficult with many kinds of plants, especially those that have small seeds. The pans should be watered as soon as sown, and after this must never become quite dry, neither must the pans be filled so full that the seeds can be washed out. Pots may be used in the absence of pans, but pots must be filled half their depth with broken crocks as drainage. Under the above treatment the majority of perennial plants may be raised from seed in a period varying from a week to two months, but, as has been already stated, many kinds are naturally slow to germinate, and the pans containing these may, during summer, be plunged in sand in a cold frame. When treated thus, less water will be required, and the soil will not become sour.

Passaic, N. J.

E. O. Orpet.

Begonia Socotrana.—When this plant was first sent out by the Messrs. Veitch, of London, a few years ago, it was warmly praised by horticulturists, and many predicted a great future for it. Every one who saw it flowering for the first time, through the dismal fog and general desolation of a London winter, was charmed with the beauty of its flowers and the healthy luxuriance of its growth; and, if I remember correctly, there were a few plants of it grown in one of the private houses in the gardens at Kew for some time before it was sent out commercially, that were shown with great satisfaction to visitors of prominence. In beauty or utility it has not degenerated since that time, and it now stands amongst the best of a group of plants that has been extraordinarily prolific of good things for garden and greenhouse. The plant is held in high esteem for the bright pink flowers it produces through the winter. It is dwarf and stocky, growing from nine to eighteen inches in height, and the flowers are borne in clusters well above the characteristic circular leaves. The leaves are smooth, of a pleasing light green shade, and average about six inches in diameter. Its cultural requirements do not differ essentially from those of other Begonias, except in the matter of resting. During the summer months, when most other species are full of vigor, this one should be completely at rest; and then about the beginning of October, the roots should be shaken out and the plants repotted in a mixture of good loam and thoroughly decayed farm-yard manure in equal parts, with a little sand and leaf-mould. Little heat is needed until the plants show signs of growth, when they should be removed to an intermediate temperature, as such an atmosphere suits them while growing better than any other. If the plants are kept close to the glass they will assume a neater and more compact form than otherwise.

Chorizemas.—Where a continuous display of flowers is required through winter attention should be given to this group of plants, for they are most attractive in the greenhouse or conservatory. The most desirable species are all natives of Australia, and thrive most satisfactorily in an ordinary greenhouse among other plants. They are hard-wooded, and of free growth. The branches being somewhat slender, however, are all the better for the support of a trellis, or stakes. In most of the species the leaves are spiny and of a dark green color. The bright colored flowers resemble those of the ordinary Pea in form, but are rather smaller. What they lack in size is more than counterbalanced by quantity, as they are produced most abundantly on the tips of the young shoots. The prevailing colors of the flowers are red and yellow, in different shades and mixtures. The most useful species are *C. cordatum*, with flowers red and yellow; *C. Henchmanii*, scarlet; *C. ilicifolium*, yellow; *C. spectabile*, orange and red. There are many other species and varieties, but these are among the best, and they afford the widest range of color. Plants raised from seed, sown soon after it ripens, always give satisfaction; but it is also possible to raise good plants from cuttings of the young wood. Some care is necessary in rooting the cuttings as they are very liable to damp off. Their general culture consists of rather hard pruning when the plants have ceased to flower, and of repotting, when they commence to grow again, in a mixture of fibrous peat, rich loam, and sand in equal parts. Care should be taken to pot firmly and to keep the roots rather confined than otherwise, as the plants flower most freely when slightly pot-bound. Abundance of air and light is essential at all times; and in summer they should be placed in the open air, that the new growth may become thoroughly ripened. Before removal to their winter quarters the plants should be tied into shape; and it will add to the gracefulness of their appearance if they are afterwards allowed to develop their flowering shoots naturally. Some growers keep all the shoots tied-in severely, but this process adds nothing to the beauty of the plants.

Botanic Garden, Cambridge, Mass.

M. Barker.

Seedling Chrysanthemums.—The perennial Chrysanthemums are so readily obtained from seed that even when one has a choice collection there is a great pleasure in trying a few seedlings with a certainty of vigorous, thrifty plants, a profusion of very varied bloom during the same season, and a possibility of a strikingly new and valuable variety. This is the proper season for sowing, which may be done in pans, pots or boxes, as the seeds germinate in ten days or a fortnight in moderate warmth. The young plants should be picked out in flats filled with a rich compost as soon as possible, and kept growing slowly at a moderate temperature, as well up to the light as possible. Shift them when necessary, the object being to secure strong, stocky plants with an abundance of good roots. Give all the air practicable

at all times, and as soon as possible harden them off without checking, so that they may be placed in cold frames to grow on slowly until chilling spring winds have ceased, when they may be planted out. The main objection to growing seedlings is that at flowering time the bushes take up valuable room, and, many being worthless, the space is more profitably occupied by varieties of approved excellence. This objection is well taken, but is obviated very readily. The most approved system among the growers now is to plant the seedlings in nursery rows, where they are easily cultivated, and allowed to grow away without removal of branches or suckers. A seedling *Chrysanthemum* is a wonderfully vigorous and thrifty plant, far exceeding in these respects a plant grown from a slip. In early June the plants are all numbered, and a few strong cuttings are taken from each and struck in a gentle bottom heat from manure. They root quickly, are shifted along into five or six-inch pots, are carefully cultivated and disbudded, and show, under this test, very closely their value. It will be seen that under this system no room is wasted, as the test takes little space; if the plant is of no value it is left out to be thrown away, but if worth propagating, one has not only the tested plants, but a good, vigorous bush full of branches and suckers, from which a large stock may be had at once, a very important point when one considers the value of new varieties of merit. The chance of securing a first-rate variety from seeds such as are ordinarily to be had is very slight, but the pleasure of watching the whole life of the plant—the germination of seed, the wonderfully thrifty growth and the amazing bloom, will repay any flower-fancier.

The Knees of the Bald Cypress.

To the Editor of GARDEN AND FOREST:

Sir.—I have read the interesting essay of Dr. Lamborn in your issue for January 8th with great pleasure. My own observations on the knees of the Cypress do not seem to me reconcilable with Dr. Lamborn's hypothesis. The objections which they raise to it are as follows:

1st. The trees on the sandy uplands need the assumed support quite as much, if not more, than those which grow on the neighboring loam—often clayey—of the inundated bottoms, yet these upland forms always lack the excrescences.

2d. While a slight upward growing protuberance would doubtless strengthen the root, the tall column exhibited by many knees would have no value in this regard.

3d. The summits of the knees normally attain a height which brings them above the level of the water in the growing season; when they cannot attain this elevation the tree fails to develop. When, by the subsidence of the land at an earthquake, or the artificial flooding of the area by dams, the crests of the knees are brought under permanent water, the condition is fatal to the plant.

4th. The fact that the Cypress-knees serve as respiratory organs is made the more probable by the existence of sharp upward flexures of the roots of the Tupelo (see "Effect of permanent moisture on certain forest trees" in *Science* (xiii., 176; March, 1889). These flexures, as there shown, are horse-shoe-shaped curves of the whole root, which, like the Cypress-knees, rise above the level of permanent water. On the Tupelo these structures are clearly of no advantage as anchors. Dr. Wilson and others have shown that similar structures exist in many plants.

I was aware that roots extended downward from the base of the Cypress-knees, but it seemed to me that the position of these roots was to be attributed to disturbance in the circulation and growth, brought about by the development of the knees rather than that the knees gave rise to the vertical roots.

Although I cannot at present agree with Dr. Lamborn in his main view, his paper seems to me a very important contribution to a discussion which promises to throw much light on the laws of plant development.

Harvard University.

The Chinese Persimmon.

To the Editor of GARDEN AND FOREST:

Sir.—I read on page 612 of the second volume of GARDEN AND FOREST a note from one of your southern correspondents relating to Japanese Persimmons, which leads me to believe that you have only the Kiki of Japan, the *Diospyros*, Si-Tché of Bunge, in the United States. But there is another and very distinct Asiatic species, the *D. Sinensis* of the same botanist,

which we cultivate at the Villa Thuret and which produces excellent fruit here.

The Chinese Persimmon is not as hardy as the Kiki of Japan, the leaves are more persistent and the habit is different. The flowers are smaller and yellower, the globular fruit does not turn red in ripening, and at maturity it is yellowish green and the size of an apricot, with sweet flesh, and generally contains several seeds. This species could, no doubt, be crossed with your Virginia Persimmon, a cross which might produce interesting and valuable results.

I have noticed that the seeds of *Diospyros* lose their power of germination almost immediately when they are exposed to the atmosphere, and, like Orange seeds, they should be preserved in the fruit until the planting season arrives.

C. Naudin.

The Western New York Horticultural Society.

The Annual Meeting at Rochester.

THIS society, which is mainly composed of progressive and successful fruit-growers, held its thirty-fifth annual meeting at Rochester last week, and the proceedings were characterized by a business-like directness and expedition which is always expected there, but rarely seen in similar gatherings elsewhere. Practical and instructive papers and discussions, together with promptness, precision and system in the conduct of business, and all pervaded by unflinching good humor and fraternal feeling, constitute a positive educational force, so that these meetings have a direct value which is recognized and appreciated. Mr. Patrick Barry, who has been the efficient President of the society for more than thirty years, was unable to attend the sessions or to prepare his usual address. He sent a letter, however, offering his resignation on account of years and infirmities, but this was met with a unanimous declaration that so long as he could sign his name he must allow himself to be considered as the executive head of the body over which he had for so long a time and so acceptably presided. It was announced that Mr. George Ellwanger had given \$1,000 to the permanent fund started by Mr. Barry last year for the society, and additional contributions increased it to more than \$4,000. Abstracts of some of the papers and notes from the various Committee Reports and from the discussions are given below, and will be continued in our next issue.

FORCING VEGETABLES UNDER GLASS.

This was the subject of an admirable paper by Professor L. H. Bailey, the greater portion of which here follows: During recent years great progress in the forcing of plants has been made in two general directions: First, in improved methods of constructing and heating glass houses; second, in the increased knowledge of the demands of particular plants. Many garden vegetables are now grown during winter with profit, and the number is constantly increasing. This business of forcing esculent plants is a special business, requiring a particular kind of knowledge and careful attention, and therefore, in common with all special businesses, it is profitable when properly handled, and it is not likely to be overdone. As a rule, the most difficult crops are the most profitable. Yet there are no great difficulties attending the forcing of plants, as most people seem to suppose. The business demands only care and thoughtfulness. The demand for certain kinds of winter vegetables is steady and is rarely weakened by overproduction. Winter gardening is a business which, in a peculiar way, pieces out and supplements the horticultural operations of the year, superseding the unprofitable link of winter idleness.

The most important advance in winter gardening lies in the improved construction of glass houses; and this consists not so much in the mechanism of the building as in the application of the laws of nature to plant growth. And this improvement has resulted not only in producing better plants at lower cost, but it has reduced the cost of building the houses. The first feature of the improvement is found in the relations of the house to light. The gardeners of a century ago were aware of the value of light for forcing plants; but they were not successful in securing it. Efforts were made in the early part of the century to construct the roof at such angles as would catch the most rays of light, for it is well known that

if the sun's rays strike glass roofs at right angles the greatest economy of light will result. The roofs were, therefore, built with such slopes that they would stand as nearly as possible at right angles to the sun's rays in the coldest months of the year. It soon became evident, however, that in the houses of most approved construction the slanting rays of morning and evening must be largely reflected. Hence, there arose various special forms of roofs designed to present some surface at right angles to the sun at all hours of the day. The most popular of these was the curvilinear roof. In its ideal conception it demands a house circular or nearly circular in form. Various fluted roofs were also devised; the most famous of which was one erected at Chatsworth, by Sir Joseph Paxton. This latter style of roof demanded so much more material that much additional cost was incurred with little gain in the amount of light. The curvilinear roof, in its modified forms, is still popular for conservatories, but it is not adapted to the forcing of vegetables.

The old-fashioned circular and dome-shaped houses have come to be historical curiosities. They possess a radical defect; the roof is too high, too far away from the plants. We are now reversing the endeavors of the old gardeners by taking our plants to the light rather than by taking the light to the plants. In other words, we must get our plants near the glass if we demand quick growth. Fifty years ago Loudon was one of the first to perceive the defects in the old houses. "It is found," he says, "that the rays of light, after passing through glass roofs, lose their influence on the plants within in proportion to their distance from the glass. Hence, for general purposes a long, narrow house is the best." Loudon's statement was largely a prophecy, and we are reaping the realization of it. The ideal form of a forcing-house is one which is long, narrow, low, and more or less flat. It is more economical in construction than the old style of house, while the results obtained are incomparably better. Every gardener knows that if he would grow good and profitable crops of any low vegetable in a house he must get his plants near to the glass. The low and narrow houses possess other advantages over the old-fashioned circular and rectangular structures. Or, to quote Loudon again, "there is another reason in favor of narrow houses where perfection of growth and economy are objects, which is, that a considerable portion of the heat by which the temperature of hot-houses is maintained, is supplied by the sun." Sun heat is better than artificial heat. The curvilinear form of roof is now combined with the long and narrow form of structure, and this gives a house of peculiar value for growing some ornamentals, because it gives sufficient height for them to grow without greatly increasing the height of the house. For the forcing of kitchen garden vegetables, however, this added height of the curvilinear roof is a positive disadvantage. And all curvilinear roofs are more expensive than direct roofs.

Of recent years we have also added greatly to the light in houses by the use of large panes of glass. The glass is also better than it was formerly. This improvement of glass lies: (1) In greater transparency, due mostly to greater thinness, and (2) In greater regularity in its surfaces. Early in the century panes 3 x 5 inches were largely used, chiefly because panes of this size could be made very thin and regular. When larger panes began to be used better results were not reached, simply because the surfaces of the glass were so uneven that much light was reflected and refracted.

The second feature of improvement is found in methods of heating. No subject connected with glass structures has been the occasion of such violent discussions during the last few years as the various methods of heating. The fact that these discussions exist is proof of progress, for agitation always means revolution or improvement. We are emerging from the old hot-water system into better and more economical methods. These later methods are steam heating and improved hot-water heating. The old style of cast iron pipes laid exclusively under the benches is being replaced by ordinary gas-pipe, whether the heat be applied by hot water or steam. In fact, the methods of piping glass houses are now almost identical in both systems. In either case the heat is carried from the furnace through one main pipe or riser which passes through the house near the top. From this riser as many returns are taken as are necessary, and the steam or water is returned to the boiler underneath the benches. About the only difference in piping for steam and hot water lies in a little more careful grading of the pipes for hot water, and the highest point in the hot water riser is usually at the further end of the house, while the highest point in the steam riser is approximately over the furnace. These systems of heating introduce a new principle into the method of forcing

plants; a part of the heat is applied above the plants rather than being entirely applied as bottom heat, as formerly. This of itself presents some advantages. It allows of greater uniformity in the temperature of the house, in proportion to the extent of heating surface, because it supplies some heat near the glass where the greatest radiation takes place. The piping under the benches is so much in excess of that above them, that good bottom heat is secured.

The common question now among greenhouse men is, which is better, steam or hot water? A Yankee would reply by asking the question what is meant by hot-water heating? If the old system of hot-water heating is meant, then I should say unhesitatingly that steam is better. But if the questioner has in mind the more modern and improved methods of hot-water heating, then I should prefer not to answer for all cases. It is undoubtedly true that for small houses the modern hot-water system is the better; and it may be that it is better in all cases. For myself, however, I have preferred steam, and I am using it in my houses. I have no doubt that the ideal system of heating is going to be a combination of steam and hot water. In other words, the ideal system will use steam whenever or wherever steam is found to be better, and it will use hot water in the same apparatus whenever hot water is better, as in mild weather. In fact, most of our steam plants can be used almost equally well for hot water. Let us suppose that we have a low pressure steam heater and that our house is piped for ordinary steam heating. When running with steam, we simply keep the water low in the furnace, so that there is room above the water for the storage of steam. If, now, upon any day I wish to heat with hot water, I simply fill my furnace full of water and run my plant as before. The expansion of the water by heat will force it through the pipes as if it were steam. There are but two or three matters of detail which demand attention. Some provision must be made for the expansion of water beyond the capacity of boiler and pipes. This expansion is provided for by simply taking out of the riser or return near the boiler a three-fourths-inch gas-pipe and carrying up this pipe several feet into a tank. The higher the tank above the furnace, the greater will be the pressure upon the hot water and the hotter will the water become. Under a pressure of forty pounds, the water will reach a temperature of about 300 degrees, which is a higher temperature than is attained by steam under any ordinary pressure. A stop-cock, preferably a stop and waste, should be inserted in the small gas-pipe near its union with the main, in order to close the circuit when steam is used. If the boiler is supplied from water-works an expansion-tank is not necessary, unless the pressure is very great, for the water may be turned on permanently and expansion will simply back the water up into the water works system. In using the steam plant for hot-water heating, the safety valve must be fastened down to hold the water in. When steam is used again it is only necessary to draw off most of the water from the boiler and to close the cocks in the expansion-tank.

inch gas-pipes are probably the best size to use in heating glass houses, because they present a greater heating surface than any other pipe which can be economically used. That is, small pipes and more of them is a better system than few large pipes. A more even and economical distribution can be secured by their use.

In practice it is found that twenty feet is about the maximum profitable width for a forcing-house. If a low house is desired, for forcing Radishes, Lettuce or other low plants, a much narrower house is advisable, unless it can be built upon a slope, where a two-thirds span can be used. Very narrow houses contain so small a body of air that the temperature is more difficult to regulate than in a wider house. The house should be low. The sides range from two to five feet, and the gable stands from seven to twelve feet above the surface in our best modern forcing-houses. The glazing is done upon permanent sash-bars, as more light can be secured by this method than by roofing with sash. The details of construction must be adapted to individual circumstances; but the old bugbear of great expense may be dismissed. I have built two good houses, each twenty by sixty feet, inside measure, at a combined cost of building, including heat, of about \$1,500. And these houses are much better than common commercial forcing-houses, which can be built much cheaper than this.

In conclusion, it may be said that there are six general essentials to successful forcing of plants: (1) Bottom heat. (2) Abundance of light. (3) Proximity of plants to glass. (4) Fresh air. We must outgrow the notion that we ventilate simply to cool off the house. The primary object of ventilation is to give fresh air, and this should be secured without allowing drafts upon plants or changing the temperature of

the house suddenly. (5) Humidity of atmosphere. (6) Adaptation of methods to change of habits in plants. Plants rarely, if ever, maintain the same habit of growth when forced as they naturally possess out-of-doors. The struggle for light is the chief cause of change of habit. It is the adaptation of methods to this change in habit and rapidity of growth which largely determines the good gardener.

THE CLEMATIS DISEASE.

A most valuable paper was one by Professor Comstock, of Cornell University, explaining the cause of the fatal Clematis disease, which has so long baffled investigation. One nurseryman in Ohio estimates his loss last year from this disease at \$4,000, and the subject is so important that we reproduce the paper almost entire:

The more striking symptoms of this disease are (1) the leaves suddenly turn black; then (2) the vine dies down to a spot near the root that has a diseased appearance. Frequently, after a period of rest, the plant will take a fresh start, sending up a new shoot from the root. But the life of this growth is of short duration; for the plant that once dies down is doomed to perish soon. At first sight there are strong reasons for locating the seat of the disease in a limited section of the vine near the ground. This section has a diseased appearance; the plant dies down to this point; and later fresh shoots are sent out from below it as if the roots were healthy. It was doubtless these reasons that led Professor Arthur to look upon a fungus which he found in the plant at this point as the cause of the disease. But my studies of the past two years have convinced me that this fungus simply accompanies the disease, and that the cause of it is something very different. Every grower of Clematis has observed knotty growths of varying size upon the roots of some of the plants. It is in these knots, or galls, that the cause of the disease is to be found. If a gall be cut across and the section examined with a hand lens of moderately high power, there will be found embedded in the abnormal plant growth small, pear-shaped bodies of the same color as the cut surface of the root, but rendered easily visible by their smooth, polished surface. These pear-shaped bodies are found on careful examination to be sacs containing a large number of eggs. In fact, each sac is the body of a worm which has become greatly distended by the eggs which have been developed within it. It is these worms cankering the roots of the plants that cause the disease. And, as they multiply rapidly, when soil becomes infested by them the spread of the disease is terrible. I know nurserymen, who a few years ago produced Clematis plants by the tens of thousands, who have been forced to give up their production on account of this disease.

But more unfortunate than the serious injury caused by these worms to the Clematis, is the fact that they do not confine their attacks to this plant. A very large number of species are liable to be attacked by them, and consequently the trouble cannot be overcome by simply suspending the production of this one plant. It is a question in which every horticulturist, whatever he produces, is interested. It seems as if the horticulturist was fated to ever have new battles to fight. He became thoroughly aroused long ago to the warfare against insects; somewhat later he awoke to the appreciation of the importance of plant disease caused by fungi, and now we find another group of animals much lower than insects preying upon plants to a serious extent.

The animals in question are worms, belonging to the order known to zoölogists as the Nematodes, or thread-worms. The species of this order that have attracted the attention of gardeners abroad are commonly known as eel-worms. A good illustration of the order is the "vinegar eel," a minute creature often seen wriggling near the surface of vinegar. The majority of the species are, like the "vinegar eel," harmless, feeding upon dead or decaying vegetable matter. A few species attack growing plants. The best known of these to readers of the English journals is the one that causes ear-cockles in Wheat in England, and the tulip-root of Oats in the same country; but more important than either of these is the species that infests the Sugar Beet in Germany. That species and the one infesting Clematis are closely allied, and differ from other forms in the body of the female being pear-shaped, as already described above; but the two species differ in that the one infesting Sugar Beet does not cause the plant to form galls like that infesting Clematis.

Both sexes of this species when young are very minute, requiring a high power of the microscope to detect them, and are thread-like in form. They can crawl very rapidly, and it is in this stage that the species is spread from plant to plant. The males undergo some remarkable changes, but are always

more or less thread-like. The females, after finding lodging places in the tissues of the roots and becoming fertilized, become distended in a remarkable manner, assuming the pear shape already described, and becoming of sufficient size to be seen by means of a simple lens.

The range of plants infested by this species of Heterodera is very great. It is already known to attack at least seventy-five species of plants belonging to widely different orders. It is found in diseased roots of Roses; it is very common in Begonias; it does a good deal of injury to Cucumbers, Potatoes and Tomatoes. In the south it is especially destructive to Peach, Grape and garden vegetables, including Cabbage, Turnip, Lettuce, Beet, Parsnip, Egg-plant and Melon. This wide range of food plants is the most discouraging element in the treatment of this disease. In fact, I do not feel that we are in condition to name with any great degree of certainty any plant on which the worms cannot live. In this direction lies an important field for future experiments. When such plants have been determined, the cultivation of them on infested ground, and thus starving the worms out, will be the most practicable way of meeting the evil in the case of field crops.

A German writer, Professor Kuehn, strongly urges the use of what he terms catch-plants against the species that infests Sugar Beet. He has used Rape as a catch-plant. This is sown on infested fields; the young worms in the soil penetrate the roots of the plants. After the roots have become infested, but before the females have begun to produce young, the plants are pulled up and destroyed. In this way several crops of Rape are produced upon the infested field one after another in the same season, each succeeding crop tending to entrap the worms remaining in the soil. But, obviously, the use of catch-plants is a very expensive method of fighting the pests, and yet it is an expense that would be gladly met by the owners of valuable lands if they could feel sure of such results as these reported by Professor Kuehn. Still I think we are hardly ready yet to give definite directions for the use of such plants. It seems to me, however, that the growers of Clematis can at once, without waiting for further discoveries, reduce their losses to the minimum by a little care in the management of their plant-houses, in the procuring of potting soil and in the choice of fields for planting out.

The conditions in some of our establishments where Clematis is grown are those most favorable for the multiplication and perpetuation of the disease. The benches upon which the pots stand are covered with gravel or coal ashes, which is changed at infrequent intervals; the roots of the diseased plants pass through the hole in the bottom of the pot and ramify in the gravel or ashes, and the worms follow the roots, infest them, and this soil becomes a breeding place for the pest. When another lot of plants is placed upon such soil, obviously in a short time these plants will become diseased. It is recommended, therefore, that between each two lots of plants the soil be carefully removed from the benches and placed where it will not contaminate other crops; that before renewing the soil the benches be thoroughly washed with lye so as to destroy any worms that may be lodged in the cracks; that the soil for potting be carefully selected so that it shall not be a source of infection; that in planting out great care be taken to make sure that it be done on land which is free from this worm; if any roots of any kind are found in the soil which have unnatural swellings upon them, the field should not be used, as there will be a strong probability that such swellings are galls made by this worm; and finally, until a grower is able to produce only healthy plants he should not use root-grafts, for roots that are apparently healthy often contain the worms.

THE EMBELLISHMENT OF PUBLIC PLEASURE-GROUNDS.

The paper on this subject, by Mr. William McMillan, Superintendent of the Buffalo parks, was one of substantial merit, and its value was made so clear by impressive delivery that the effect on the audience was striking. After speaking of the necessity of having a consistent plan, Mr. McMillan insisted upon thoroughness of construction; everything should be of the most durable character, since the admission of makeshift and temporary work always proves costly in the end on account of the greater cost of maintenance. In a consistent plan all features will not only be in proper harmony with each other, but nothing will be introduced that cannot under ordinary municipal conditions be easily maintained in good condition at all times. For instance, the location, width and alignment of drives and paths will combine to the best advantage, gracefulness of proportion and convenience in use. The sinuosity of a walk, if unnecessary or unnatural, will surely tempt pedestrians to make a cross-cut track at every

bend. This will not only disfigure the grounds, but encourage disorderly usages that will gradually lead to other encroachments, until the original design be obliterated and its ornamental value be utterly lost. For similar reasons, the more ambitious or pretentious any decorative feature may be, the greater the risk of incidental damage that will make it a mockery of the motive with which it was introduced. Whatever general type or special feature of embellishment may be desirable, the measure with which it can be fittingly maintained will be the best gauge of what may wisely be attempted. This measure will be of a different standard for public grounds from that current in well-kept private gardens. The conditions differ more widely than is generally believed. Private grounds are almost wholly free from a large class of petty trespasses that are the constant accompaniment of public use or occupation. Park policemen may be appointed to prevent such damage and to secure orderly behavior, but in practice they are often an expensive luxury more ornamental than useful. Trespasses that in the aggregate may be fatal to all decent management, taken singly may seem so petty as to be unworthy of notice. Stepping on forbidden grass, dodging out and in through bushy thickets, breaking twigs, picking flowers, peeling saplings, girdling Birch-trees, carving Beech-trunks, even downright stealing of small plants, or their wanton destruction, may be of daily occurrence without detection, or, if detected and gentle reproof be unheeded, sterner action will be resented and arrest be worse than useless. Take a flagrant case to court, and the plausible lies and special pleading that will be heard and believed will make the misdemeanor seem too trivial to occupy the time of the court.

Those untoward conditions make it prudent not to indulge freely in showy or costly ornamentation. Take, for example, the culture of Azaleas or Rhododendrons. When they are in bloom the temptation seems too strong for the average park visitor. They will be despoiled at every favorable opportunity, and soon the plants will be entirely destroyed, as from two to three years' growth of twig will go with every flower-truss that is plucked. Natural conditions of soil and situation suggest a sheltered and shady location, but there the risk of depredation is greatest. Constant police supervision is impracticable, and the safest place will be the most exposed and frequented; but there you must fight against sun and wind, drought and frost. Of the two evils you may choose the less, but only to meet constant vexation and disappointment and final failure.

After explaining why a formal and artificial scheme of planting may be the most effective in small city squares, Mr. McMillan argued against the use of trees and plants with highly colored foliage, where broad effects were aimed at, as unduly exalting the abnormal above the normal, the rare-freak above the common type. It is surely false to Nature to do so, or to run to excess in the display of strange colors, however natural the tints may be. Nature is always temperate in the display of high color. The rainbow is evanescent. Dew-drops sparkle only at a certain angle of vision, and soon evaporate. A gorgeous sunset covers but a small part of the heavens, and lasts but a few minutes, and the exhibition is not opened daily or even weekly. For a week or so in autumn there is a brilliant display of colors in the foliage of trees and shrubs; but the duration of the brightest tints in any leaf is very brief, and the whole display is but "a fleeting show." Because we can admire these changing colors so much for a brief period as the foliage ripens, it does not follow that we could enjoy the display with equal relish if exhibited during the whole season of active vegetation. As a daily diet, it would surely satiate, and even nauseate, the most hungry appetite for high color.

Mr. McMillan's paper contained many other valuable suggestions, to some of which we shall refer in the future.

Recent tests indicate that London Purple may be more dangerous to foliage when used in spraying than Paris Green, because it sometimes contains more soluble arsenic.

In Chautauqua County 8,000 tons of grapes were produced last year, which, at so low a price as three cents a pound, were worth nearly half a million dollars. In Yates County 7,500 tons were produced.

Hyposulphite of Soda, though not a perfect remedy for the scab of Apples or Pears, is still the best that is known, and when a mixture of half an ounce to ten gallons of water is used it will destroy a large proportion of the fungus.

The high price of sugar materially lessened the demand for many kinds of fruit during the last season. This was particularly true of Currants, but the price of Strawberries was also

affected because the preservers used comparatively few of them.

It was generally held that an orchard of Dwarf Pears is more profitable than one of standard trees. Dwarf trees had proved long-lived, yielded as good if not superior fruit, were less susceptible to blight and bore more regularly. Dwarf Pears could be planted on heavier soil—indeed they should not be planted on light, sandy ground, which is not naturally adapted to the Quince root. The Duchess had heretofore been used almost exclusively as a dwarf, but the Kieffer was now largely worked on dwarf stock, and the Anjou and Howell were named as varieties especially adapted to this treatment. One orchard of four and a half acres yielded 441 barrels of Duchess pears last season, which brought \$1,906. The practice is to cut back severely every year and fertilize heavily.

The movement in favor of fruit-growers' institutes was commended because, it was argued, this industry was quite as important as others in which instruction was provided by the state. If dairy institutes are held in the grazing districts of the state to the advantage of butter-makers, cheese-makers and milk-producers, there is equal reason to suppose that local meetings for discussion in the fruit-growing districts at which experts in various branches of fruit-culture could read papers, would prove helpful. If it is essential to weed out from the dairies of the state unprofitable breeds of cattle, it is quite as important to discard unprofitable varieties of fruit. The average yield of apples in the state is less than one barrel to the tree, and individual trees under the best conditions have borne ten barrels and even more than twice ten barrels, according to the veteran Major H. T. Brooks.

Notes.

Trailing Arbutus was found, last week, in full bloom, in two places in the neighborhood of Mays Landing, New Jersey.

As evidence of the advanced state of the season in South Carolina, Dr. Mellichamp sends us a branch of the old *Morus multicaulis*, gathered on the 18th of January, with expanded flowers and full grown leaves.

A European correspondent, who has traveled in Ceylon, calls our attention to the fact that a plant mentioned in a notice of an article from *Macmillan's Magazine* on "Weeds" on page 611 of our last volume is not, as the English writer supposed, the blue-flowered *Ageratum*, but *Lantana curavatica*.

A correspondent from Minnesota writes that a Tamarac tree (*Larix Americana*) has lately been found which measured seven feet eight inches in circumference four feet above the ground, and was estimated to be 125 feet high. The largest Cedar (*Thuja occidentalis*), observed by the same correspondent, measured ten feet four inches in circumference at four feet above the ground, and was about seventy feet high. Both these trees grow near a brook of constant spring water, and in alluvial soil, rather stony.

A monster Elm-tree stands on the Avery Durfee farm in Wayne County, New York, between Palmyra and Marion. Two feet above the ground it measures thirty-three feet ten inches in circumference, and five feet above the ground twenty feet and ten inches. It is sixty feet to the first limb and the total amount of lumber in the body of the tree is 16,250 feet. Eighty years ago, when the farm was cleared, this tree was left as a landmark. It was then a giant among the surrounding forest trees.

About 20,000,000 pounds of prunes are annually produced in California, largely of the better quality, which are packed in fancy boxes like the high-grade French prunes. In our eastern cities the California fruit has sold, of late, in much larger quantities than the French, and at prices from three-quarters of a cent to one cent higher per pound. But between 60,000,000 and 70,000,000 pounds of inferior foreign prunes are annually imported, to be sold at very low prices to the laboring and mining population of all parts of the country.

According to the London *Times*, the largest market for Christmas-trees in Germany is Berlin, where, this season, 400,000 trees were sold, varying in height from two to thirty feet. At wholesale, the plants are bought by the *schock*—that is, in parcels of sixty, large and small ones being taken together as they come, at an average price of from about \$5 to \$5.50 per *schock*. At retail, trees not more than two feet high sell for twelve and a half cents. From seven to ten feet is the size most in demand, which brings from twenty-five to fifty cents, while twenty-foot specimens of fine quality bring \$2.50 or \$3. Almost all are Fir-trees, cut in the Hartz Mountains.

It hardly needs to be said that the persons who appreciate landscape beauty, and who recognize the superiority of free natural treatment, or what is known as the park-like treatment of extensive public grounds, have as keen a relish for what is commendable in ornamental gardening as those who seem to consider it the only kind of gardening worthy of the name. Our belief is that the most refreshing antithesis to the hard lines of straight and stony streets shut in between high walls and to all the stress and pressure of city life is found in the freedom and openness of simple, broad, meadowy landscapes and spacious skies. And yet we have given illustrations of many formal gardens to show how effective they may be where skillfully planned and adapted to their surroundings. Fit fields for work of this sort are offered in most of our cities in connection with public buildings and elsewhere. Along Riverside Drive, in this city, where the foreground is limited by the parapet, there is ample opportunity within this line for ornate embellishment, statues, fountains and floral embroidery, and all this would not detract from the impressiveness of the prospect across the strong and silent river, with the forest-crowned cliffs and noble sky-line beyond. This means that while we would exclude ornamental gardening from places where it cannot be displayed to best advantage, and where it would clash with the design of other works, it is

altogether proper that adequate provision should be made for it in appropriate places at public cost.

In speaking of both these types of gardening-art, we have referred of course to genuine art and not to any spurious imitation or substitute for it. Only a master endowed with the creative faculty in ample measure could, with the material at hand—common grass, common shrubs and trees—work out a landscape so complete and satisfying as that in the Buffalo Park, the very strength of which is its simplicity. Almost as hard to find is an artist with the constructive talent and refined sense of color and form which will enable him to conceive and carry out a creditable design in strictly ornamental planting. When the writers who can see no beauty in a natural landscape, and insist upon higher color and more elaborate form in planting, will point out some satisfactory examples of this kind of work, or state with definiteness what it is they wish to substitute for the American flags and carpet-patterns and ribbon-lines now prevalent, they will command the gratitude of every one interested in garden-art.

There can be no doubt in the mind of any one who has given the most casual attention to forests and forest requirements that the productive capacity of any piece of woodland in this country can be increased by the application of a little common sense to its care, or that the wealth of the country can be increased enormously by the general introduction of wise systems of forest management. Men, or the great majority of them, who own woodland or forests will take care of them only when they can be made to realize that there is money in doing it, and not before. They must be made to understand that certain systems of culture must be applied to the care of land covered with trees as well as to land covered with other crops. Every authoritative word about our forests which is written or spoken with this object in view has its value. The strongest arguments are those based on facts like these in the following extract from a communication made by Mr. J. D. Lyman, of Exeter, New Hampshire, to the *American Cultivator*:

"The proper care and management of our Pine-forests must be in the line of experience and actual facts. Theory will not answer alone, nor are the writings of European foresters always safe guides in American practice. I will give you a few simple facts in illustration.

"I have in mind a clump of Pine-trees, which I remember from childhood, for it stands close by the burial-place of relatives of mine. An aunt of mine remembers these Pines in her childhood, and she was born in 1802. It is safe to say that they are 100 years of age. These Pines came up thick, and have never been thinned out, except as, in their struggle for existence, some have been so shut out from sunshine and crowded as to die. They are yet so small that I have never heard any one refer to these trees as being a clump of timber. They are tall and almost limbless, stunted, spindling trees, and I think very few of them one foot in diameter.

"In the winter of 1854-55 I bought a hundred-acre lot of land covered with a light deciduous growth, with small White Pines scattered among it. A very few years before the previous owners had cut out all the Pines large enough for small framing timber. It is well known that small trees are cut for this purpose. I paid \$600 for the lot, and was laughed at for giving so much. I commenced to cut Pine-timber upon this lot in the winter of 1862-63, and in five years had taken \$1,900 net from it. In 1870 I sold the remaining saw timber upon it for \$600 on the stump. This illustrates how rapidly scattering Pines will grow.

"In January, 1870, I bought a lot and cut the Pine upon it closer than I ever cut them for timber on any other lot. I cut trees not much over six inches in diameter. A gentleman rallied me about putting cord-wood in as logs. About four acres of very thick little Pines were left after cutting close as I have stated, and more or less Pines, so small as to escape even such close cutting, were left scattered over perhaps twenty acres. In 1873 or 1874 I commenced to have these little Pines thinned out. This thinning has gone on from time to time till the present. Much wood, shingle-stuff and small timber has been cut out, all of which has paid well for cutting, so that the thinning has cost me nothing. And now my larger Pines on

this lot are much larger than the largest in the clump first referred to near the burial-place, though only about one-third as old. I think the Pines on this lot would to-day sell for from five to ten times as much as they would have sold for if they had not been thinned.

"These and many other instances convince me that it is very easy in many cases to increase the growth of timber some four-fold upon our lands, and have the thinnings which are cut out pay or more than pay all the expense of the necessary labor. On the second lot I have mentioned, the Pines were so scattered and the other growth so small that the Pines had got above the other trees and grew rapidly without aid. As a physician may kill with good medicine unwisely administered, so one may almost ruin his grove by injudicious thinning. I have seen such instances. Yet the proper thinning of thick young trees is of very great importance."

The Problem of Heather in North America.

FEW wild plants in the British Islands and on the continent of Europe are more attractive to American visitors than the very common Heath or "Heather" (*Calluna vulgaris*). The moors of the north are brightened by its color, and there seems to be no end to the prodigality with which Nature has scattered in barren places these clusters of delicate foliage and far more delicate blossoms. To the dwellers on the edges of the wastes carpeted by Heather the plant is hardly more than a hold-fast to bind down drifting sands, since sheep and cattle do not willingly use it as food. And it is not unlikely that much amusement has been caused by the expressions of delight which have fallen from the lips of Americans who have seen for the first time Heather in profusion. Although the present writer has many times seen Heather, and perhaps enough of it, in different parts of Europe, the sight of the plant when bound together as stable-brooms or used as bedding for cattle has never ceased to appear as a sort of an indignity against which he ought to remonstrate.

The reason for this feeling on the part of Americans is plain enough. In the first place, the plant is pretty, despite its commonness everywhere in the old world, and, in the second place, it does not grow, and cannot be made to grow, "wild" in our own country. Here and there, as we shall see presently, it has been found in small amount, but it has had only a precarious hold upon the soil, with no assurance that at any place as yet unvisited our botanists will find it well established.

This lack of Heather here seems all the more strange when we remember that the climate of the north temperate zone is substantially the same here as on the other side of the Atlantic. Making all allowance for the differences produced by the influence of the Gulf Stream, which gives to the west coast of Europe a warmer climate than we enjoy at the same latitude, it is hard to see why this plant, so common there, should be wanting here. We must ask, if at one time it covered the northern hemisphere, where has our share of it gone, and if it never was here at all, why does it not invade our territory, as so many of the other common plants of Europe have done, and which we call weeds? In the last century the great Linnaeus wrote that two plants threatened by their spread to cover the whole earth—namely, Tobacco and common Heather. Tobacco has made pretty good progress, but so far as Heather is concerned his prophecy has not been in any marked degree fulfilled.

So far as the Heath family, as a whole, is concerned, we may say that in our country we have a fair share, but that of the true Heaths themselves we have practically none at all. At Nantucket two species have been found, but in such small amount and under such circumstances that no one thinks of regarding them as native plants.

The true Heather (*Calluna vulgaris*) was early reported as occurring in Newfoundland, but Mr. Charles J. Sprague, who investigated the evidence upon which one of the citations rested, was forced to decide against its authenticity. Other localities have, however, been found since, both in Newfoundland and in the Provinces of New Brunswick and Nova Scotia, but in all instances the space covered in each locality has been reported as rather small, and in a few of the cases there was strong suspicion that the plants had been introduced by man.

In July, 1861, Mr. Jackson Dawson exhibited at one of the weekly meetings of the Massachusetts Horticultural Society a plant of Scotch Heather, which he had labeled "Native Heath, found growing wild within twenty miles of Boston." A committee of the Society made a careful examination of the locality. From their report communicated to the *American Journal of Science*, January, 1862, p. 22, a few facts are here-with given. The plants grew over about half an acre of

even pasture-land, which was covered by a close, short grass, and interspersed with numerous plants of Sheep-laurel, Hardhack, Cassandra, Sweet Gale, Cranberry and a few Alders. There were twenty or more old plants and a multitude of seedlings springing from the peaty soil, mixed with sand, which was well adapted to the cultivation of any Heaths. The earth was kept moist by a brook running through the meadow, and here the plants flourished. A thorough investigation of all the circumstances connected with the growth of the plants showed that it was extremely improbable that they had come from seed sown by man, and the committee concluded that the plants were indigenous. Professor Gray visited the locality in September in company with a member of the committee, and he, likewise, came to the conclusion that the plants were native.

Subsequently a small locality was detected in the neighboring town of Andover and another in Cape Elizabeth, Maine.

Somewhat over a year ago the writer had the pleasure of visiting the Tewksbury locality in company with one of our most assiduous devotees of botany, Mr. Walter Deane, of Cambridge. At the dwelling-house nearest the locality we obtained explicit directions as to the exact spot, and we walked with confidence, expecting to see that the Heather had perhaps spread over a larger area in the twenty-seven years that had elapsed since Dr. Gray's visit. On the way to the brook we saw a vigorous clump of Heather, which had evidently been transplanted from the larger locality, and this removed any doubt we might have entertained as to finding the original place. Our utter discomfiture can therefore be realized when it is stated that we hunted high and low, up the brook and down the brook, and even far into a neighboring young forest, without detecting a trace of the plant. We were both rather accustomed to hunt for rare plants, and did not feel inclined to give up the search easily, but at last we were forced to return to the house for further instructions. Here we learned that we had been indeed in the right place, and, to prove this, the owner of the land went with us to point it out. On reaching the place with us he walked back and forth through the Alder-bushes, and at last declared that he could not account for its disappearance. To be sure, the place had been visited by many persons who had carried away reasonably large specimens for transplanting, but this would not explain the utter extermination. A few straggling, "drawn," prostrate and dying specimens were finally found, but they were only mere shadows. All that we could do was to make a pecuniary arrangement with the owner to clear away the overshadowing Alders and other young shrubs, and give the remnant a chance. But the chance appeared to be indeed a very small one, hardly worth even a day's labor. Such seems to be the history of about all the localities of Heather known to us in this country. For instance, a well-established locality discovered by the writer a few years ago on the line of the Maine Central Railroad, in Westbrook, Maine, and known to a few members of the Portland Society of Natural History, has been entirely lost by fires along the track. Some of the stations in the provinces have held on rather better, but the plants do not appear in any case to spread over more ground. Uncared for, the plants are speedily crowded out by more vigorous contestants for the space, and they give up the unequal struggle.

Late in the summer of 1888, I received some excellent specimens of Heather from a lady living in Townsend, Massachusetts, a town near the New Hampshire line. I have visited this locality twice, in company with other botanists, and on the last occasion accurate measurements of the area covered by the plant were made. Without giving details, it will suffice now to state that considerably more than an acre of ground was found well filled with healthy, strong plants, and that there was every indication of their being in full possession. The only rivals were the low bushes, common in what is everywhere known in New England as a Blueberry-pasture. The sandy soil had a few strong Cranberry-vines, but against these and the grass-like plants the Heather was evidently making its way. There were also a few plants of species of *Viburnum* and *Cornus* as well as of those seen in the Tewksbury station, but they did not appear threatening, nor did the one or two trees. The Heather was spreading into adjacent fields and even invading the woods near by. In short, the locality impressed all who examined it as one likely to be long preserved.

The question is again brought before us, by this new and strong station, as to the relations of this plant to our flora. The proximity of the station to that in Tewksbury and the lost one in Andover, suggested that the three might be the fading traces of a general occupation of a large area. It was with a measure of disappointment that the information was received which emptied this suggestion of all its value. Upon learning

that there was a good degree of interest in the matter, the owner of the land said that he could tell us how the plant came there. About the time of the Franco-Prussian war, his sister-in-law visited the north of Ireland and brought back as a souvenir a few sprays of Heather from her old home. In the box holding these dry sprays were some seeds which it was suggested should be sown near the homestead in Townsend, but it was finally decided that the Cranberry-pasture would give the seeds a better opportunity for growth. Here the seeds were sown and the rapid growth had taken place in the period of sixteen years which had elapsed. In the pasture the browsing and grazing animals had kept down the competitors of the Heather, and with the happiest results. The moisture of the land was enough to provide for the plants the water which, in the Old World, they get from the humidity of the atmosphere over the moors (that is, the moisture in the air, condensing on the plants, must make partly good the lack of moisture in even the dry sand there), and so the Townsend Heather had kept its place.

There would seem then to be much encouragement in these facts for our dwellers in country homes. Given a barren pasture with a fair amount of moisture in the soil, and given, also, some means of keeping down the shrubs which would crowd the Heather out, the plants will have a fair chance of surviving. It seems possible that many of our country and even our seaside pastures may be made attractive in this way, at least the experiment is so promising that it should be fairly tried.

While, therefore, I believe that with a little help in keeping its competitors under, Heather may be made to thrive under conditions easily attainable here, I can no longer believe that the scattered stations of Heather now existing in the provinces, and, more rarely, in New England, date farther back than the accidental or intentional scattering of Heather-seeds by the hand of man.

We have, in such a study of Heather in a New England pasture, a capital illustration of the paucity of simple facts at one's command. What we do know, is the following: A common plant, wild in a soil and in a climate much like our own, refuses, under the ordinary conditions of the struggle for existence, to make even a pretense of holding its ground when it comes here. What no one knows, is the following: Whether the conditions here, of heat and cold, dryness and moisture, insect visitants, competing shrubs and herbs, grazing animals, and the like, are so nearly favorable that with a trifling change, one way or the other, they might serve the plant well and give it here an open welcome. Careful observation of a few plants of Heather, left to themselves in different localities in New England or the middle states, might settle some of these points which otherwise must be left, as now, to mere conjecture.

George Lincoln Goodale.

Cambridge, Mass.

New or Little Known Plants.

Picea Breweriana.

WE are indebted to Mr. J. G. Lemmon, the botanist of the California Board of Forestry, for the photographs from which the illustrations of this California Spruce on pages 66 and 67 have been prepared. *Picea Breweriana** is the most local of all the Spruces and perhaps from its peculiar habit of growth one of the most remarkable of them all. It was not noticed until 1884, when Mr. Thomas J. Howell, of Arthur, Oregon, found it on the north slope of the Siskiyou Mountains near the head waters of the Illinois River, in the extreme northern part of California. It was seen later by Mr. T. S. Brandegee (who obtained a trunk of this tree for the Jesup collection in the American Museum of Natural History in this city), a little to the south of Howell's locality on one of the small north forks of the Klamath. These are the only stations known for this remarkable tree, and there are hardly a hundred fully grown individuals in them both, although it will be found, doubtless, on some of the adjacent ridges or mountain-ranges; for all that part of California lying west of Mount Shasta, one of the most broken and rugged parts of the state, is still very imperfectly known and its botany is practically unexplored. Mr. Brandegee found the few trees which he saw, widely scattered over an area of several hundred acres, growing with the Douglas Fir, the Sugar

*Watson in *Proc. Am. Acad.*, n. ser. XII, 378. Sargent in *Gardeners' Chronicle*, n. ser. XXV, 493, f. 93.

Pine, the White Fir (*Abies concolor*) and a few small specimens of Lawson's Cypress which, previous to that time, was not known except in the single locality discovered by Jeffrey on the head waters of the Sacramento below Mount Shasta and on the Oregon coast.

Picea Breweriana differs from the other American Spruces by its blunt, round leaves and by its larger cones, whose thin, entire scales resemble somewhat those of the White Spruce; they are much larger, however, and sometimes almost as large as those of the Norway Spruce, which this tree resembles, too, in the form of the leaves and in its long pendulous branchlets. These long branches, one of which, very much reduced of course, appears in figure 16, are the marked and striking feature of this tree. They are six or eight feet long sometimes, thin and flexible as a whip lash, and "give to the trees," to use Mr. Brandegee's expression, "the appearance of Weeping Willows." The cones, instead of appearing near the top of the trees as they do in the other American Spruces, are produced from the lower branches also, as in the Norway Spruce, and hang down from the ends of the long pendulous branchlets. The largest tree measured by Mr. Brandegee was ninety feet high, with a trunk diameter of thirty inches.

Neither Howell, nor Brandegee, nor Lemmon, the only botanists who have ever seen, apparently, *Picea Breweriana*, visited the trees at seasons of the year when seeds were ripe, and this species has not been introduced yet into cultivation. *Picea Breweriana*, if it is fair to judge from the habit in cultivation of several other California trees which grow naturally only in small numbers and in very narrow areas—*Cupressus macrocarpa*, *Pinus insignis*, *Pinus Torreyana*, *Chamaecyparis Lawsoniana*—may be expected to adapt itself to conditions very dissimilar to those in which it is found on the Siskiyou Mountains and to thrive outside the limits of its present restricted range. If this expectation is confirmed and *Picea Breweriana* assumes in cultivation anything like its normal habit of growth, it will certainly prove one of the most striking and attractive American conifers and a garden ornament of first-rate value.

The specific name adopted by Mr. Watson for this tree commemorates the services, in California, of Professor William H. Brewer, of Yale College, who, more than any man in his generation, has brought to light by explorations in the forest the characters and distribution of the Pacific coast conifers.

Foreign Correspondence.

London Letter.

TWO new Irises are now flowering for the first time at Kew; they are *I. Bakeriana*, a near ally if not a variety of *I. reticulata*, which it resembles in habit, size and form of flower, but differs most markedly in color from the known forms of that species, and is superior to them all. It is pale blue, with white falls spotted and blotched with rich black velvety purple. At Kew it thrives under the same treatment as *I. reticulata*. The second one is *I. Bornmulleri*, an Armenian species introduced last year by Max Leichtlin. Its habit is that of *I. Persica*; the flowers are medium in size, and colored a deep canary yellow, with a few brown spots on the outer segments and slightly bearded. The inner segments are unusually narrow and small for an Iris. Close to these two Irises is the bed of spring flowering Crocuses, many of which are in full bloom already. Lately the weather here has been quite spring-like. On Sunday, the eighteenth, for instance, the thermometer stood about sixty all day, and the sun shone as brightly as in May. The mildness of the weather so early in the year is almost certain to have disastrous consequences. *Lonicera Standishii* and *Hamamelis arborea* are in full bloom, the former a white flowered, very fragrant and free blooming plant of semi-scandent habit; the latter a beautiful shrub, with its twiggy branches thickly clothed with bright golden flowers.

NEPENTHES.—A collection of pitchers of these plants, just shown by Messrs. Veitch, was, perhaps, the most interesting exhibit of the first meeting of the Royal Horticultural Society. The pick of this fine collection are *N. Curtisii*, *N. hirsuta*, *N. Northiana*, *N. Rafflesiana* and *N. sanguinea*. Many hybrids were shown, the best of them being *N. Mastersiana*, *N.*

Dicksoniana, *N. Morganæ* and *N. Chelsoni*. As a rule, the hybrids are very much easier to cultivate than the species. Probably the very best garden plant in all the lot is *N. Mastersiana*, raised by Messrs. Veitch from *N. sanguinea* and *N. distillatoria*, and grown by them into really marvelous specimens.

Hippeastrum aulicum, var. Prince Albert, is an old Chatsworth favorite, and certainly the best of the several forms known of this fine plant. Flowering at this time of the year, this species is of special value, and it is one of the easiest to manage of all *Hippeastrums*. The flowers are large and colored deep crimson, strong bulbs producing scapes two feet high, bearing three or four flowers. *Dendrobium Macfarlanei*, shown by Messrs. Veitch, is a new introduction from Torres Straits, with the pseudo-bulbs and foliage of its geographical neighbor, *D. superbiens*, whilst the flowers, almost as large as those of *D. formosum*, are snow white. The petals and sepals are rhomboid, two inches long, the lip being almost as long, with two acute folding lateral lobes, bearing a few streaks of purple.

DENDROBIUM HYBRIDS.—These are becoming abundant in English gardens, and, unfortunately, some of them differ from each other only in name, while not a few are inferior to the commonest species. A hybrid should be a distinct gain, or it should be destroyed. Of course there are hybrid *Dendrobiums* which are both distinct and beautiful; such, for instance, are *D. Ainsworthii*, and *D. splendidissimum*, var. *grandiflorum*, the latter, however, very unfortunate in having a ridiculous name. Sir Trevor Lawrence exhibited at the meeting of the Royal Horticultural Society, held on Tuesday last, the following hybrid *Dendrobiums*: *D. Luna* (*Ainsworthii* × *Findlayanum*), like the last-named parent in habit and in the size of the flowers, but having creamy-white segments with purple tips, a large lip with a few purple lines in the throat, and a tinge of yellow in front. It scarcely differs from *D. chrysodiscus*, a hybrid raised from the same parents, and it is slightly better than *D. xanthocentrum*, which was obtained from *D. Findlayanum* × *D. Wardianum*. This has large flowers like those of the last-named parent, but the lip is large, flat and yellow in the middle, as in *D. Findlayanum*. *D. Juno* (*Wardianum* × *moniliforme*) is simply a good *D. nobile*, with the addition of a tinge of yellow on the labellum. *D. chlorostele*, from the same parents, scarcely differs from *D. Juno*. The finest of the lot was *D. splendidissimum grandiflorum* (*aureum* × *nobile*), which flowered for the first time some ten years ago. The flowers are over four inches across, of good substance, and like a gigantic *D. Wardianum*, except in the lip, which is shaped like that of *D. aureum*, but larger, and colored rich velvety purple, margined with white. This hybrid is remarkable on account of its exceeding both parents in size. *D. enosmum* (*endocharis nobile*), and its variety, *leucopterum*, have elegant large fragrant flowers, the variety especially being a charming Orchid, pure white, with a rich maroon-colored lip.

D. nobile, grandest of the race, beautiful even in its worst form, a perfectly tractable garden plant, and possessed of endless variety in form and shade, was represented by some rare forms from the collection of Sir Trevor Lawrence. These were *D. Cooksoni*, the three-lipped *Dendrobium*, its three inner segments, or petals, being alike in size and color, the lowest one being less spreading than the others; it is an interesting and beautiful Orchid. The Burford Lodge variety is even more interesting morphologically, as the characters which normally belong only to the lip occur also on the lower half of the two lateral sepals. *D. Tolliana* is a curious monster, the flowers being inverted so that the lip is uppermost; the petals are broad and less spreading than is usual in the species. If we add to these the grand varieties known as *nobilis*, *Sanderianum*, *pendulum*, *Wallichianum*, etc., every one as easy to manage as the commonest form of *D. nobile*, the value of this species in gardens is plainly seen. *Dendrobiums* are not general favorites; a few, such as the above, *D. fimbriatum*, *D. formosum*, *D. thyrsiflorum* and *D. Dalhousianum*, are popular, but there are dozens of first-rate garden plants in the genus besides these, and many of them are just as easy to manage. The species in bloom now at Kew are *D. Wardianum*, *D. nobile*, *D. speciosum*, *D. moniliforme*, *D. Ainsworthii* × and *D. formosum*.

MEXICAN LÆLIAS.—The gayest Orchids in flower now are such Lælias as *L. anceps* in many varieties, *L. albida*, *L. furfuracea*, *L. Gouldiana* and *L. Crawshayana*. Better acquaintance with these plants makes it clear that, as in the many forms of *Cattleya labiata*, which once ranked as species, as in the case of these Mexican Lælias, there are more species recognized than can be easily maintained. The link connecting *L. albida* with *L. anceps* is the rare *L. Crawshayana*, called

a natural hybrid, but probably merely the link needed to unite these two extremes under one heteromorphous species. The same remark applies to the newer *L. Gouldiana*, which connects *L. autumnalis* with *L. furfuracea*. Of course nature is not concerned in making species and keeping them distinct; one might easily proceed from this to argue that every genus is merely one variable species of more or less range. We must believe that all the species in a genus have sprung from one, pretty much as all Cabbages are from *Brassica oleracea* and all Chrysanthemums from *C. morifolium* (*Sinense*). At any rate, the term natural hybrid for a plant with a fixed and distinct character seems to me lame. Talk about names merely is, however, an unprofitable game, for a gardener at any rate. If I could have my way plant names should be fewer in number and very much simpler than many of them are now. The man who saddles plants with names like *Damnacanthus*, *Catoblastus*, or *Swammerdamia*, is guilty of something akin to felony.

MIDWINTER CHRYSANTHEMUMS.—These are useful, and efforts are being made by the National Chrysanthemum Society to encourage their production and culture. A paper read this week at a conference of this Society recommended the following as possessing the qualities most essential, namely, lateness in blooming, which must, of course, be inherent and not the result of special treatment; secondly, freeness of habit and convenience of size; and thirdly, good, well-colored, freely produced flowers—*Etoile du Midi*, *Kämpfer*, *M. C. Hubert*, *Meg Merriles*, *Ralph Brocklebank*, *Countess of Lytton*, *Ceres*, *Mrs. C. Carey*, *Ethel*, *Thunberg*, *Boule d'Or*, *Moonlight*, *Gloriosum*, *Mrs. H. Cannell*, *Golden Gem*, *Boule de Neige*, *Snowdrop* and *Mdlle. Sentir*. These, according to the author of the paper, do not begin to bloom before the beginning of December, and they remain in beauty at least until the middle of January. He also recommends the following single flowered kinds as possessing the same qualities, namely, *Magenta King*, *Canariense*, *Brunette*, *Ellen Terry*, *Mrs. Killock*, *Monte Carlo* and *Gus Harris*. Other late flowering kinds deserving of special mention are *Kioto*, *Lord Eversley*, *Moonlight* and *Maggie Mitchel*. The treatment recommended for these late flowering kinds by an excellent grower here is as follows: Strike the cuttings in March or April, shade in hot sunny weather, and half plunge the pots in ashes. Do not house the plants until forced to do so by frost, and when under glass keep them as cool as possible. If the flowers are not pushing fast enough a little heat may be given in December.

London.

W. Watson.

Paris Letter.

IN spite of the cloudy and disagreeable weather which has prevailed this winter in central and southern Europe, Tea Roses, Narcissus and Australian Acacias from Provence are sold in our streets, with Violets, also from the south, of which an incalculable number of little bouquets are sold at prices varying from two to five cents each. Forced Lilacs, Lilies-of-the-Valley and Snowballs are the most common flowers in the florists' shops. The forced Lilacs have for many years been objects of considerable commercial importance in the French capital, and now the cultivation of Lilies-of-the-Valley becomes every year more and more extensive. The beauty of the flowers, their durability and the delicacy of their perfume make the Lily-of-the-Valley one of the favorite flowers here. The roots for forcing come from Belgium. Attempts to force those taken from the woods have never been very successful, and it is found necessary, in order to obtain good flowers, to subject the roots to preparatory cultivation in nurseries. It is estimated that about 1,500,000 roots of Lily-of-the-Valley are now forced every season in the neighborhood of Paris, and that the average annual sales of the flowers amount to half a million of francs.

Cyclamens, different species of Erica, the Clivias, and Chinese Primroses, Cinerarias, Hyacinths, Tulips and Epiphyllums appear also in the windows of the florists.

At the last meeting of the National Society of Horticulture, M. J. Sallier, of Sceaux, exhibited a fine specimen of *Luculia gratissima*. This superb shrub belongs to the *Rubiaceæ*. It is a native of Nepaul, and therefore should be cultivated in the cold house. The rose-carmine flowers are extremely and delicately fragrant, and are united in great terminal corymbs. Like so many other plants, *Luculia gratissima* was fashionable at one time, and then its cultivation was abandoned without any apparent reason. The world has its caprices, but it does no harm to call attention from time to time to neglected plants often difficult to obtain, although, fortunately, they still exist in the great botanical gardens. M. Sallier exhibited also *Cypripedium chloroneurum*, a hybrid, whose parentage is unknown.

It has the foliage of *C. venustum*, and great brilliant flowers, looking as if they had been covered with a coat of varnish, and *C. Enanthum*, a hybrid between *C. Harrisianum*, crossed by *C. insigne Maulei*. The foliage of this plant is dark green. The peduncle is covered with black hairs, and bears a solitary flower, whose superior sepal is greenish white, with numerous violet veins, the petals and lip being vinous violet. M. Chantrier, of Bayonne, exhibited seedling Chrysanthemums; M. Driger, a *Cælogyne*, introduced directly from Burmah; Vilmorin & Co., an interesting variety of *Calceolaria*, obtained by crossing *C. rugosa* with a herbaceous species. This hybrid has the advantage of being a perpetual bloomer. M. Baltet exhibited before the Committee of Ornamental Arboriculture several shrubs in fruit. The most conspicuous were *Coton-easter tomentosa*, *C. Nepalensis*, *C. horizontalis*, *Cratægus Carrieri* and *C. Crus-galli*, *Lycium Sinense*, *Rhodotypos kerrioides*, *Ligustrum Iboia*, *L. vulgare* and *Diospyros Lotus*.

Two interesting plants have recently found their way into commerce here. One is the *Genista Andreana*, of which Croux & Sons, of Val d'Aulnay, near Sceaux, have purchased the stock. This plant was found growing wild in Normandy with *Genista Scoparia*, of which it is only a variety with red-flowered wing-petals, which make a good contrast with the bright yellow of the other parts of the flower. This plant was described and figured in August, 1886, in the *Revue Horticole*, and was exhibited in Paris last summer. The *Genista Andreana* is a sand-loving plant, but it can be cultivated on clay soils if it is grafted on the common Laburnum. The second new shrub is *Euscaphis staphyloides*, introduced into commerce by M. Lemoine, of Nancy. It is closely related to the *Staphylea*, which it much resembles in its general habit. It is a native of Japan, where it is known as *Gonzui*, *Kitsune no tsija Cukun* and as *Dai i noki*. It is often cultivated in Japanese gardens, where it grows to a height of ten or twelve feet. The small greenish white flowers are produced in terminal panicles and are followed by a fruit which becomes scarlet at maturity and remains upon the plants until the beginning of winter like the fruits of *Euonymus*. According to Siebold, the inner bark of the roots of *Euscaphis* is bitter and astringent, and is used by the Japanese as a remedy against dysentery.

Paris.

D. Bois.

Cultural Department.

Lælia anceps.

THIS is undoubtedly one of the very showiest Orchids in cultivation. It is exceedingly popular, very plentiful and cheap, and therefore to be met with in every collection, even where Orchids are not a specialty, but where a place is retained for a few of the best cultivated varieties. The popularity of this species is not to be wondered at, when it is considered how valuable its large, handsome flowers are in enlivening the somewhat dreary aspect which naturally presents itself in our plant-houses during the sombre months of November, December and January—the season when *Lælia anceps* and its many beautiful varieties are always to be found in bloom.

The typical *L. anceps* is distinguished by having ovoid-fusiform, more or less angled pseudo-bulbs, which are from three to six inches long, and closely arranged on the rhizome. A single oblong-lanceolate, very leathery leaf, six to eight inches long, is borne on the summit of each pseudo-bulb, whence also emerges the peduncle. This latter is one and a half to three feet long, having at each node a more or less silvery-looking, keeled and sheathing bract, the tip of which just passes the base of the bract above and opposite to it. From two to five flowers are borne on each peduncle, and these, if spread out, would measure between five and six inches across. The sepals and petals are deep rose, the former being lanceolate-acute, the latter much broader and elliptic-lanceolate. A peculiar feature of the sepals—also to be observed in *Lælia pumila*—is that the upper one slants back without being recurved, and the two lower ones slant forward on each side of the lip. The side lobes of the latter organ are folded over the column, forming a tube. They are pale rose outside, creamy white inside, with interrupted lines of dark purple, which vanish in the magenta-purple of the recurved anterior portions. The middle lobe is reflexed at the tip, and of a deep magenta-purple, which presents a vivid contrast to the elevated disc, which is of the brightest yellow and bordered in front with white. The column is white behind, tinged with green and streaked with purple, and green in front, spotted in the centre and lined with purple on each side.

There are many very fine varieties of this species. One of the least known and, at the same time, one of the most distinct, is that known, as *Amabilis*, which first flowered at the beginning of last year with Messrs. Sander & Co., St. Albans. The sepals and petals are of the clearest white, occasionally flushed with rose. The lip is tinged with yellow, and has a mauve-purple blotch on the white mid-lobe, while the side-lobes are very conspicuously streaked with crimson. *L. anceps Barkeriana* is a very old but rare form, having been introduced by Messrs. Low & Co. in 1837. The flowers are of a deep rose-purple color, with narrow petals and lip. The variety *Dawsoni* is almost universally acknowledged to be the finest form of this species. The sepals and petals are of the purest white, the latter being remarkably broad, and the front lobe of the lip has a blotch of magenta-purple in front of the yellow disc. *L. anceps Sanderiana* is something like this, and is, by some, preferred to it. It flowers very freely. The sepals and petals are pure white and much larger than in the ordinary *L. anceps*. The side-lobes of the lip are stained with yellow and streaked with dark purple, and the front-lobe has a magenta-purple blotch shading off into white at the edges. *L. anceps Ballantineana* appeared for the first time this year in Messrs. Sander's nursery. It is very beautiful, being remarkable for its large flowers; the sepals and petals (the latter being very broad) are tipped with rose, and the front lobe of the lip is of a much darker magenta-purple than any form yet known. *Veitchiana* is a lovely variety with white sepals and petals, and a large mauve-purple blotch on the lip. The form *Percivaliana* has white sepals and petals flushed with lilac. The side-lobes of the lip are deep rose-purple in front with darker purple streaks on each side of the yellow crest. In front of this is a white area and then the deep magenta-purple front lobe. There are many other forms, such as *alba*, *vestalis*, *Hilliana*, etc., but it is almost impossible to depict their beauty and distinctness from each other in writing.

To the now obsolete firm of Messrs. Loddiges, of Hackney, is due the introduction of *L. anceps* to cultivation in 1835, and Messrs. Low & Co., of Clapton, were not far behind, as they soon afterward imported it. It is a native of Mexico, and I think I cannot give a better idea of its surroundings in that country than by quoting from Mr. Kienast-Zolly, of Zürich, who, writing in the *Gardeners' Chronicle* in March, 1887, says:

"During my long residence in Mexico I have many a time found plants of *L. anceps* growing in my Coffee plantation in the neighborhood of Cordova, in the state of Vera Cruz. I always met with them on the borders of the virgin forests, growing on the trunks of trees and on the very slender branches exposed to a powerful sun and to strong winds, often also clinging to the rocks covered with the remains of leaves and moss under the same conditions. During the rainy season—from May to October—these plants are daily drenched by the torrents of rain, of which they experience the full force, often for five consecutive hours, and are thoroughly wet throughout the night. About six o'clock in the morning a sharp and fresh wind, coming from the highest peaks of the Cordilleras—many of which are capped with perpetual snow—begins to dry the plants, a work which the burning sun completes, pitilessly shining on them for several hours until the daily storm drenches them afresh. Under these conditions *L. anceps* grows with extraordinary vigor, and flowers about the end of October or November; just at the time when the new bulbs arrive at their perfect development. Some weeks after the rainy season is over the newest bulbs become firm and ripe, so as to prepare for a

thorough and necessary rest, which lasts until March, when the new growths appear."

Mr. Kienast-Zolly further remarks that *L. anceps* is widely distributed along the eastern side of the Cordilleras, from Jalapa southward to Orizaba, where many varieties are to be met with, and also in some places along the Pacific coast.

From the above remarks on this species in its natural con-

Fig. 15.—*Picea Breweriana*.—See page 63.

dition, it will not be hard to judge the kind of treatment it requires under culture. The plants are generally grown in baskets, as more convenient for hanging up, and the compost used is rough peat and chopped moss mixed with corks or charcoal. Of course the drainage must be good. From March until August or September, when the plants are growing vigorously, they may be well watered every day almost, and receive as much light and air as possible, but not allowing the sun to scorch them by means of the glass roof, as would inevitably happen on hot days if slight shading were not used. After this period the flower-spikes push up, but do not produce flowers for a month or two longer. The supply of water must then be diminished little by little until the flowering season is at an end, which is generally about the middle or end of January. The plants should then enjoy a thorough rest until growth again begins. The temperature in winter may sink as low as 50° Fahr. during the night, but may reach as much as 60° or 70° during the day. In the summer these figures will naturally be some degrees higher—especially in the day-time—in both cases.

John Weathers.
St. Albans, England.

Chives.

THE bulbs of this vegetable increase by offshoots, or bulb-lets, which multiply rapidly during the growing period. It is not generally cultivated, a rather surprising fact when its ease of culture, hardiness and vigorous growth are considered. It will grow even in partial shade, and with the exception of the Onion-maggot, which will sometimes work among the roots, it has no dangerous insect enemies. It is perfectly hardy in all soils not filled with water. It grows at a low temperature, and hence is used for early salads in spring, and can be cut almost as soon as the frost is out of the ground. It responds promptly to heat and careful culture, giving a constant and rapid supply of its tender leaves, which are most acceptable wherever the flavor of Onion is desired. My first plants, a clump of perhaps fifty of the small bulbs, were divided into ten parts and set in the ground in spring. Here they grew rapidly, increased in size, till fall, when I had ten bunches as large as the one divided in spring. These re-

mained out all winter without protection, and during the second season made clumps of roots six inches across. In the fall three of the roots were lifted, with the ball of earth attached, and carried into the cold cellar, and here the tops disappeared and the roots appeared to die. In the month of February these roots were brought into the warmth of the greenhouse, and placed in the soil at a temperature of about fifty degrees

at night and seventy by day. They started at once, and in six weeks from the time of setting in the ground the tops were large enough for use, and were clipped close to the ground. The roots sent up a new growth, which was ready for cutting again in another six weeks. As soon as the supply on the open ground appeared the cutting was stopped from the roots in the house, and when settled weather came these roots were again planted out-of-doors, where they again grew with vigor. At the close of the season they were well established, and in the fall the roots for forcing were taken from those undisturbed the previous year.

The plant under consideration is the smallest member of the Onion family in cultivation. It makes a nice appearance, continuing green all the season, and in midsummer has a seed-stalk crowned with a purplish flower cluster, not unlike a Clover-head. The plants grow very evenly to a height of six or eight inches. It rarely develops seed in this latitude, and consequently is best propagated from the roots, which bear transplanting well and grow in all soils. The roots grow fairly well in pots, and if plunged in the ground in summer and rested awhile in fall, can be grown and flowered in the window.

Fig. 16.—A Branch of *Picea Breweriana*.—See page 63.

Lælia albida.—This charming little Orchid will be seen in bloom in nearly every collection about this time, and is justly valued for its spikes of delicately-tinted and fragrant flowers. It is well adapted for cut flower or bouquet work, and lasts a considerable time in water. *L. albida* is found very abundantly in the southern part of Mexico, generally at considerable elevations. It was introduced nearly sixty years since, and has always been a popular Orchid. Its cultural requirements have not as yet been thoroughly understood, for no matter how good and strong the imported plants

may be, they surely dwindle away in a few years, and fresh supplies have to be brought from their native habitat. The best success has been attained by giving them abundance of air and sunlight, plenty of water during growth, and rest in a cool, dry house.

Notes from the Harvard Botanic Garden.

CYCAS REVOLUTA.—A large specimen of this Cycad has been in fruit in the Palm-house here for several months, and it has proved of much interest to visitors. Last spring a series of little leaves—downy and yellowish, from six to twelve inches in length, and altogether different from the regular leaves—appeared upon the crown of the plant; and some weeks later the fruits appeared upon the sides of these leaves, being arranged singly along two-thirds of their length, and leaving a somewhat fasciated cluster of leaflets at the top. When young, the fruits are hard and present the same downy appearance as the leaves upon which they are borne; but with age the exterior covering becomes soft, and the fruits assume a brilliant vermilion hue that can be easily seen through the loose downy covering. In size and form they resemble a large flattened prune, with two lobes at the top. Some time ago a visitor spoke of them as tiny peaches a little deformed, and there is some accuracy in the comparison. Though these fruit-clad leaves add very materially to the appearance of this beautiful plant, their production has a decidedly injurious effect upon it, inasmuch as the development of the pleasing dark green leaves is thereby considerably retarded. In the ordinary course of events specimens that bear a crop of fruit will not assume their normal appearance for two or three years. As this plant is commonly known as the Sago Palm it is believed by many that the sago of commerce is obtained from it. This is an erroneous idea. It is true that a substance with the peculiarities of sago may be obtained from the pith in the trunk; but the genuine sago is a product of *Metroxylon Sagu* (*Sagus laevis* and *S. Rumphii*), an entirely distinct Palm, from the East Indies.

GREVILLEA THELEMANNIANA.—The genus *Grevillea* includes many handsome plants, but this species is by far the most interesting. It is a dwarf shrub, of bushy habit and most graceful outline, from Australia. The branches are slender, though self-supporting, and thickly clad with fine, feathery foliage of a glaucous hue. The flowers are borne in dense globular clusters at the extremities of the young shoots, and, as the slender branches arch outward gracefully with their weight, the clusters, at a distance, look like huge tropical insects hanging from threads. The individual flowers are small and of a bright red color, and the long, slender pistils, of the same color, with conspicuous green stigmas, add considerably to the beauty of the flowers. The plant is almost constantly in bloom, but the flowers are produced most freely during winter and spring. With proper attention to soil and other necessities it will thrive satisfactorily in any greenhouse the temperature of which is not allowed to fall below forty-five degrees. It may be readily increased from cuttings of the young wood placed in a propagating frame any time during spring. Established plants may be cut back slightly during the latter part of spring, and if a shift is required it may be given when they commence growth again. Two parts fibrous peat to one of turfy loam and one of sand forms a suitable compost.

MANETTIA BICOLOR.—At the present time this is one of our most attractive stove climbers. It is a plant seldom seen outside botanical gardens, and that cannot be due to its novelty, for I saw it well grown on a globular trellis, in a private collection, a dozen years ago. It can hardly be said that lack of merit is the cause of neglect, for it is a very showy thing when liberally treated. Nor are its cultural requirements so exacting that a novice in the management of stove plants may not attempt to grow it. As the slender twining stems rapidly cover a given space, it is a most useful plant for training on rafters, pillars or trellis work of any description. The tubular flowers are small, but their brilliant red and yellow colors render them very conspicuous. They are borne in the axils of the leaves on the young shoots. Their production is periodical, and when a crop is past the plant should be given a short season of rest, after which it may be pruned slightly and again allowed to grow and flower. If planted in a bed or border, the drainage should be ample, and it would be well to confine the roots to some extent, as members of this genus tend to the production of leaves at the expense of flowers, when the roots are allowed to ramble at will. A mixture of strong loam, fibrous peat, leaf mould and sand will be found satisfactory.

Pot bound plants are benefited by an occasional watering with liquid manure.

OXALIS VERSICOLOR.—This old favorite among the many beautiful species of *Oxalis* appeals for a word in its favor as its flowers open in the morning sunshine. It is a delicate little plant, with its three inches of slender stem, surmounted by little clusters of tender leaves and lovely flowers. The petals are pure white, with the exception of a faint tinge of yellow inside, at the base, and a narrow but showy margin of bright crimson on the outer half of each. This species is usually described as having a corolla white inside and red outside; but any one who takes the trouble to examine carefully a fully expanded flower will soon find this description incorrect. The flowers cannot be seen fully developed, however, unless the sun is shining, and even then the plant must be so placed that the sunlight falls directly upon it; otherwise the flowers will remain closed or in a half opened state. Perhaps the inaccurate descriptions are partly due to this fact. A casual glance at a folded flower might give the impression that the outside of the petals is wholly red. But, whether the flowers are folded, half opened or fully expanded, they are very beautiful. If the roots are planted thickly over the entire surface of the soil in pots, or, better still, in shallow pans, the plants will form a compact mass of flowers and foliage. If planted sparsely they present a straggling and untidy appearance during the following season.

Preparation for Bedding.

AS the spring approaches, preparation will be in order for out-door decorations in the way of bedding, and many new plans and new plants will doubtless be considered. The list of plants available for this purpose has been largely extended of late years, not merely by the introduction of new ones, but also by the discovery from year to year that various plants, not before used to any extent in this particular field, are perfectly adapted to it. For bedding, and especially for sub-tropical bedding, there appears to be a growing interest, and as a varied effect is usually sought for, a large number of species and varieties may be used. Of course groups of a single plant are often effective. There are many places where, for instance, a large mass of bronze-leaved *Cannas* or a clump of *Arundo donax* may be just the ornament needed.

Among the old plants not often seen is *Humea elegans*, a truly elegant plant when in good condition, and peculiarly effective in a sub-tropical bed, its graceful feathery-looking inflorescence of brownish red being very attractive, and forming quite a striking contrast with the large light green leaves, which are somewhat similar in character to those of Tobacco. *Humea elegans* is propagated from seeds, which are best sown in the autumn, so that the plants may attain considerable size before planting out, an operation which should always be deferred until settled warm weather, or about June 1st in this latitude. This plant grows well in a light, sandy soil, well enriched, and the young stock should not be allowed to become very much pot-bound at any time, else the loss of the lower leaves usually follows.

Acalypha Wilkesiana (or tricolor) is also a striking plant when used outside in summer, growing as freely as a *Coleus* and about as easily propagated. *Acalypha marginata*, the leaves of which are quite large and showy, being brown or bronze in the centre and surrounded by a light colored margin, may be used in the same manner, and with equally good effect. Cuttings of these plants should be put in now, and if placed in a warm house they will root in a few days. The *Acalyphas* are not fastidious as to soil, but they do well in good loam, to which may be added a small proportion of peat if convenient, to make the soil a little more open. Last summer I observed a large circular bed planted with *Begonia semperflorens* surrounded with a ring or edging of *Acalypha Wilkesiana*. The *Begonias* were covered with flowers and the contrast was decidedly pleasing.

A striking plant when in flower is *Lasiandra macrantha*, its large bright purple flowers being most showy. It seems a pity that the flowers of this handsome plant should be of so ephemeral a character, seldom lasting for more than a day out-doors when the weather is bright, but still they are produced in such profusion that the plant is seldom out of bloom during the summer. This plant has not been largely used for bedding purposes, though its adaptability was proved a number of years ago. The idea which once prevailed, that the *Lasiandra* was essentially a stove plant, was dispelled long ago.

If not already sown, seeds of the Abyssinian Banana (*Musa Ensete*) should be sown at once, so that the plants may be strong and vigorous before planting out. The Musas require

liberal treatment, and should not be planted out until the ground gets warm. It is always advisable to plant them in a somewhat sheltered location, for when exposed to the full force of the wind the foliage becomes so torn as to sadly mar its beauty.

Among the toughest of plants, both for bedding in summer and also for conservatory decoration in the winter, are the *Strelitzias*, the leaves being so strong in texture that they are seldom injured by storms. The best known variety, *Strelitzia Regina*, produces its odd-shaped and brilliantly colored flowers quite freely, and invariably attracts much attention, the combination of colors, bright orange and blue, being an infrequent one. *Strelitzia augusta* is a stronger grower than the preceding, and larger in all its parts, the leaves being borne on long petioles and having some resemblance to those of the so-called "Traveler's Joy" (*Ravenala Madagascariensis*). Both of the above-mentioned *Strelitzias* are natives of the Cape of Good Hope, and may be propagated from seeds, when these are to be had, or by division of the plants.

The improved Cannas of recent introduction have deservedly attracted much notice during the past season, and will doubtless be planted in large quantities for the coming summer. The Cannas are unquestionably at the head of the list of large bedding plants, and when they combine, as in the above-mentioned improved race of varieties, large and highly colored flowers with handsome foliage and comparatively dwarf habit of growth, they become doubly desirable.

Holmesburg.

W. H. Taplin.

Cannas as Annuals.—While Cannas for many years have been among the most ornamental of garden plants, the recent addition of the French hybrids, with their brilliant flowers, has added much to their value and attractiveness. Many named kinds with large flowers; brilliant reds of various shades, and yellows, some of them spotted with red, are now offered. But Cannas are so readily and soon to be had from seed that unless some special color is desired in quantity it seems scarcely worth while to bother with wintering old roots. Seeds of Crozy's Cannas, to be had of the seedsmen, will produce many of the named kinds exactly and give a good range of colors. Now is the proper time to sow them in order to secure fine plants in May. The seeds should be lightly filed through the hard outer coating, which should be softened by soaking in tepid water for twenty-four hours, after which they may be sown in moist soil, and kept in brisk heat until germination, which soon takes place. I have had good success by sowing seed in a pot which was placed inside a larger one, this being plugged to retain moisture, and the space between pots being filled with sand, and all covered with a glass and placed on the pipes. After germination the plants should be potted into good soil, well supplied with moisture (after the roots commence to run, of course), and they soon make great headway. Stocky plants two feet high may be had in late May. I do not find this strain of Cannas to be dwarf, however, as under fair culture only they will grow to the height of five or six feet.

Correspondence.

An Example in Tree Planting.

To the Editor of GARDEN AND FOREST:

Sir.—For some years during my connection with the Michigan Horticultural Society, forestry topics were sandwiched in among the other subjects upon the programmes of conventions upon the theory that the continuous success of horticulture in our state was intimately connected with the conservation of our timber areas. The discussions seemed to be fraught with little good, because the papers were either looked upon as simply interesting or stigmatized as "hypothetical nonsense, with no foundation in practical affairs of rural life." And worst of all, in the discussions the severe utilitarians seemed usually to have the best of it. That is, the men who argued from figures that more income could be derived from the cleared land than would furnish all the wood products the area of timber could produce, carried more weight than the tree-lovers, whose argument always touched upon a longer foresight, somewhat ignoring the immediate turning of a penny.

I became a good deal discouraged about awakening an interest in the subject; and although I could see disastrous effects from the clearing away of the timber in southern Michigan, I could not convince others.

Circumstances gave me an opportunity in 1878 to sow several rows in the garden west of my house with the seeds of

three varieties of Maple, two of Ash, two of Elm and one of Alder. I also planted seedlings of Norway Spruce, Austrian Pine, Arbor-vitæ and European Larch in parallel rows alongside. I cultivated them, and they grew thriftily. In the meantime, to the westward of me for miles, the timber gradually disappeared, until the wind now has a sweep for a long distance, with nothing to break its force. It was not later than 1883 that neighbors began to inquire if I would sell some of those ornamental trees. I had none for sale, but gradually began thinning out the plantation and giving plants to my neighbors. The school-ground was planted with some of the surplus; numbers found their way to the cemetery; rows of them were planted along the highway. It seemed marvelous how many could be spared and still how many remained. The grove has thickened and made a complete barrier. Many of the trees are twenty feet in height; and weekly, almost daily, in the winter season, I hear the remark, "What a complete protection the grove makes for your buildings from the force of the prevailing winds."

Shrubs and tender plants are grown under the lee of this grove that will not withstand the severity of the open blast. My coal bill is lessened, my general happiness and that of my friends admirably subverted. I have been enabled to contribute to the especial wants of my neighbors in a delightful way. Others have appreciated the argument and have followed my example. The logic of deeds has been more convincing than the argument of words.

Worms in Violet Roots.

To the Editor of GARDEN AND FOREST:

Sir.—The report of Professor Comstock's paper before the Western New York Horticultural Society upon the Clematis Disease has particularly interested me, for my investigations have led me to ascribe a part, at least, of the Violet disease to the same or a similar cause. Several fungi, as for example *Ascochyta Viola*, Sacc, *Cercospora Viola*, Sacc, and a *Peronospora*, have been found; but these did not account for all the trouble. For example, in some beds dwarfed and sickly plants would be found that did not show the presence of any fungus. Such plants, however, when pulled from the soil showed peculiar enlargements upon the roots, and these galls, when sliced and placed under the microscope, exhibited all stages of what seems to be a species of *Heterodermis*. Since this location of the trouble of such sickly plants in the roots where the Nematodes breed and rob the Violets of their vital juices, I have visited a number of Violet growers, all of whom had the sick plants, and in every case the worms have been found in the roots. Other growers have been reached through the mail with a request to examine the roots of any sick plants, and they report the finding of the root-galls.

It therefore seems clear that to the Clematis, as determined by Professor Comstock, and the Peach, Orange, and a long list of other cultivated plants, as worked out or reported upon by Dr. Neal,* of the Florida Experiment Station, and Professor Geo. F. Atkinson,† of the Alabama Experiment Station, the cultivated Violet must be added as a plant liable to attacks from these eel-worms. The two large and fully illustrated bulletins, just at hand from the south, and the paper by Professor Comstock, make it evident that there is a large field for the economic helminthologist.

N. J. Experiment Station, January 31st, 1890.

Byron D. Halsted.

A Rare Buttonwood.

To the Editor of GARDEN AND FOREST:

Sir.—Usually we expect to find our native Buttonwood-tree in ground which is at least damp. Much more frequently it is seen hanging lovingly over some stream of fresh water, or shading a country spring-house while the roots dip into the spring itself. Very rarely, however, do we see it on the tip-top of a high (and from all external signs), dry hill. If we should observe one in such a position we should expect to find it small for its age, and giving plain indications that the site was not the one best suited to its needs.

Recently, however, in Chester County, Pennsylvania, I measured one, which was growing in high, dry ground, which was, at two feet from the ground (just below its first limbs), twenty-one feet and eight inches around. One limb was ten feet and four inches around, and another eleven feet and five inches. The spread of the branches was something over ninety feet. Its height was about eighty feet.

*"The Root-knot Disease of the Peach, Orange, and Other Plants." Bulletin No. 20, Division of Entomology, U. S. Department of Agriculture, 1889.

†"Nematode Root-Galls," December, 1889.

The tree is quite vigorous, and shows no signs of declining strength. There is near by another, probably larger, specimen on lower but quite dry soil.

University of Pennsylvania.

Abraham's Oak.

To the Editor of GARDEN AND FOREST:

Sir.—Allow me to add the following to your account of Abraham's Oak (vol. ii., page 602), which I find in Hones' "Early Day Book," vol. i., p. 507, published in London in 1866:

"We are told that this Oak was standing in the fourth century. Isidore affirms that when he was a child in the reign of the Emperor Constantine he was shown a Turpentine-tree, very old, which declared its age by its bulk, as the tree under which Abraham dwelt; that the heathen had a surprising veneration for it, and distinguished it by an honorable appellation. Some affirm that it existed within the last four centuries.

"At the dispersion of the Jews under Adrian, about the year 34, an incredible number of all ages and sexes were sold at the same price as horses in a very famous fair called 'the fair of the Turpentine-tree,' whereupon the Jews had an abhorrence for that fair. St. Jerome mentions the place where the Jews were sold as 'Abraham's Tent,' where, he says, 'is kept an annual fair very much frequented.' This place, on Mamre's fertile plain, is alleged to have been the spot where Abraham entertained the angels."

The allusion to the Turpentine-tree indicates, perhaps, some other tree rather than the Oak now known as Abraham's Oak, possibly some leguminous tree, or perhaps the Lotus, *l'arbre des Lotophages* (*Zizyphus Spina-Christi*).

Boston, Mass.

Francis Skinner.

The Western New York Horticultural Society.

The Annual Meeting at Rochester.—II.

TO our report of the meeting in last week's issue we add abstracts of a few more of the papers read. Besides these papers there were reports from each county, which contained practical hints of great value to fruit-growers. The exhibition of fruit was smaller than that of last year, but it contained a remarkably fine collection of Pears from Ellwanger & Barry, among them a group of Cox's Seedlings, which have rarely been seen. These were all fine looking Pears and they promise to keep later than any of the varieties now cultivated.

LATE EXPERIENCE WITH INSECTS INJURIOUS TO ORCHARD AND GARDEN.

Dr. J. A. Lintner, State Entomologist, in treating this subject, said that a great impetus had been given to the study of economic entomology by the experimental stations, thirty of which have enrolled an entomologist among their faculty, some of them the most distinguished in the country, so that there is every prospect that within a few years the most injurious insects will be brought under control. The stations give opportunity to test the preventions and remedies under varied conditions of soil, climate, season, etc. This increase in the number of working entomologists and the enlarged fields for their research has led to the organization, during the year, of the Association of Economic Entomologists, whose aim is to co-operate, so that duplication may be avoided.

The force pump now plays a most prominent part in operations against insects in orchard and garden. The ease with which the codling moth can be controlled, and apples grown of full size, perfect form, rich in color and of highest flavor, and resistance to early decay, is sufficient proof of its value; and by its aid we hope to defy the Plum curculio, and check the ravages of almost every insect feeding upon the foliage of trees, and a large number of those which attack the products of our gardens. No orchardist or gardener can afford to do without a force pump. It is costly neglect. The cheap and fatal spray, compared with old methods of fighting, is as a gatling gun compared with a flint-lock musket.

Experiments have shown that stronger mixtures of arsenical poison have been used than necessary, and that in no case need they exceed the strength of one pound of the arsenite to 200 gallons of water. The foliage of fruit-trees has at times been injured by insecticides, so that the minimum amount of

arsenite should be used that will suffice for its purpose. Experiments for determining this will be a portion of the work for the ensuing year. It would seem that the arsenites are more liable to injure foliage which is advanced than when it first appears. If this fact is established, the mixture for later spraying should be weaker. Different fruit-trees are susceptible to the poison in different degrees. Apple and Cherry are least affected, Plum-trees are more susceptible, and Peach is most easily injured. For Plums one pound of the arsenite to 250 or 300 gallons of water should be used, and for Peaches the latter dilution is recommended.

Water as an insecticide has been used by Mr. L. C. Howard, of the Entomological Division at Washington, effectively against the Rose-slug. Rose-bushes covered with slugs were treated with tobacco soap, which killed them, but stained the petals; pyrethrum mixed with flour also killed, but it was expensive; sifted coal ashes were effective, but destroyed the looks of the bushes; then the garden-hose was turned on and a strong stream of water directed to the foliage each evening, and the bushes remained green and beautiful. The stream of water was also used against plant-lice on Currant-bushes, web-worms on shade-trees, and ants which built little mounds on the lawn and in the cracks of a brick walk; and best of all, it broke up the nests of the English sparrows in the Ivy and over the windows. Dr. Lintner has confidence that a coarse spray of water thrown with force will destroy many pests besides these. It will be efficient against the little white Rose-leaf-hopper; against the several species of the small leaf-hopper which infests the Grape-vine; as well as all plant-lice which can be directly reached. Rain-storms arrest attacks of the Apple-tree aphid and the Hop-vine aphid. If these insects can be knocked by a jet of water from their food plant while their beak is inserted into it they will die if the smallest portion of the tip of the beak is left behind in the plant.

The recent working out of the life-history of the Rose-bug at Washington may, when published, aid in the operations against it; but Dr. Lintner has long thought that the most successful means of contending with this pest is to be found in the study of its breeding-grounds. It is a local insect, appearing suddenly in immense numbers and in particular localities, and there is therefore reason to believe that it has its particular breeding-grounds. A lady in Virginia states that year after year the Rose-bugs come in myriads from a brush-covered swampy bit of sand that is always wet and was once in a bed of a river now flowing in another channel. They are true to their date of appearance each year, true also to their line of flight, which she has mapped out. They move in a body five hundred feet broad up the old river bed as far as a point indicated on the map. The second day they rise higher in continued flight, spreading somewhat and reaching certain points beyond, and their progress for two or three days thereafter can be almost certainly predicted. If more data of this sort could be gathered we might learn something of the breeding grounds of this insect.

In June, 1888, Mr. Barry's newly set Pear-trees were attacked by an enemy which was found with one end inserted into the fruit. The depredator was the larva of a small tineid moth of the group known as case-bearers, from the small case which they construct for their covering while in the caterpillar stage. The case is never deserted by the larva, but is carried about upon its body, and from it the head is thrust out to feed, and in this instance the head and front segments are buried into the fruit, the case projecting and appearing as if a bit of small twig had been stuck into the pear. Specimens of the fruit show that the caterpillar bores a hole of about the diameter of its body, that of an ordinary pin, to the depth that it can protrude from its case; withdrawing, it removes a space, and again burrows until many holes were drilled into each pear. One pear of half an inch in diameter showed forty-four borings. Of course this means destruction to the fruit, which becomes as it grows gnarled and unfit for use. Detection of this attack explains the cause of much unsightliness and deformity in apples and pears which, from the different character presented at a later stage, had been a perplexing mystery, and no one had been able to refer it to any known insect. A month later some Duchess pears from another part of the state showed a defect which Dr. Lintner at once recognized as caused by this insect. It is probable that this attack will be widespread and the cause of injury can now be traced. If the insect appears in injurious numbers it can be destroyed by spraying with an arsenite soon after the setting of the young fruit.

Dr. Lintner gave some interesting facts relating to the pear-blight beetle, a new enemy of Quince-blossoms, the Peach-bark burrower, the Cherry-tree slug and many other pests

which have made themselves conspicuously disagreeable during the year, and gave also the cheering information that a large plant-insect, identified as a *Podisus*, had been found preying upon the Currant-worm, a fact which encourages the hope that this annoying pest may be more easily controlled.

TESTING VARIETIES OF FRUITS.

Mr. C. E. Hunn, of the Geneva Experiment Station, gave an interesting account of the work in this direction under his charge, and the conditions under which new varieties were received from originators, protected from rival growers and finally reported upon. The paper concluded with the statement that there were now under comparative trial at the Geneva Experiment Station the following varieties of fruits: 300 varieties of Apples, 120 of Pears, 97 of Plums, 53 of Cherries, 151 of Grapes, 98 of Strawberries, 57 of Raspberries, 24 of Blackberries, 24 of Currants, 16 of Gooseberries. These are reported on as they come into bearing, with as full a description as possible.

Of the Strawberries tested at the station in the season of 1889, the following were found promising: Burt's Seedling, a good substitute for Wilson; Bomba, Crawford, Daisy, Enhance, Farnsworth, Hoffman, Haviland, Ivanhoe, Middlefield, Augur's No. 70 and Warfield.

For market the following are commended: Haviland and Hoffman, early; Daisy and Burt's Seedling, medium; Bubach and Crawford, late.

For the kitchen-garden the following are promising: Bomba and Haviland, early; Ivanhoe, medium; Farnsworth and Middlefield, late.

There were fruited on the station grounds the past season 1,000 seedlings, many of them crosses. In the study of them many interesting facts have been obtained, among which are the following in regard to pollen bearing blossoms: Of forty-six seedlings from Wilson all had perfect blossoms; of seventy-four seedlings from Daniel Boon, forty were perfect and thirty-four were pistillate; of fifty from Crescent, eleven were perfect and thirty-nine were pistillate; of forty from Sharpless, thirty-nine were perfect and one was pistillate; of forty from Old Iron Clad, thirty-seven were perfect and three were pistillate; of sixty-five from Crescent, crossed with Lennig's White, thirty-five were perfect and thirty were pistillate; of thirty-four from Crescent, crossed with Sharpless, nine were perfect and twenty-five were pistillate.

While the chance seedlings afford a lesson in variation, it is the crosses that should be studied. It would naturally seem that a variety as vigorous and well supplied with pollen as the Sharpless would be more potent to carry its pollen bearing quality than one of the habit of Lennig's White; but the contrary is the case in this instance, and the contrast seems too sharp to be merely chance. If this potency continues to hold good through other tests, it will be a great benefit to the experimenter in perfecting any pistillate variety, as in the case of a very late pistillate kind, of rank growth, vigorous habits and free blooming qualities, but blooming after all the pollen bearing varieties have passed out of flower. If we can be sure of a perfect variety of weaker growth, but potent to carry its pollen, it will be one step toward accomplishing our ends.

THE PLANTING OF SCHOOL-GROUNDS.

A paper on this subject by Mr. John J. Thomas began by assuming that if attractive surroundings in a home are better than those which are repulsive, certainly it is better that children should live under the influence of surroundings that are orderly and pleasant than among those that are rude and debasing. There are 5,000,000 children of school age in the country, and it should be a matter of concern to know the character of the place in which they spend a large portion of five days at least of every week at a period of life when they are most susceptible to all impressions. It certainly is better that the school-house and grounds should be attractive rather than unrefined and comfortless. And yet there are many school-houses whose appearance and arrangements are calculated to give lessons in anything else than in order and tidiness and beauty. Mr. Thomas spoke of a region through which he once drove where he passed two farms with brick barns which cost from \$6,000 to \$8,000 each, and within a mile of these, on a side road, was the school-house which the children of the owners of these barns attended. The building had originally cost, say \$400, including the rail-fence which surrounded it. It had never been painted. There were no shade-trees about it. It stood bare and comfortless, and the only comely thing on the premises was a neatly dressed school-mistress, seen through the window. Now, suppose these men, who were willing to spend thousands of dollars on buildings in which their animals were housed, had been willing to pay a little attention to

the ornamentation of the grounds where their children were receiving instruction, is it not to be presumed that the influence of a pleasant shrub-bordered lawn and some well kept shade-trees would have helped in the formation of proper habits of thought and a proper recognition of what is lovely in nature and in art? The decoration of school-grounds can be made at a trifling expense. The ground in the beginning should be thoroughly broken and harrowed and then seeded to grass. It should be planted with some native shrubs and trees, and the boys and girls should be made to feel an interest in maintaining it. The play-ground proper may be in the rear of the building, and if the students are furnished with a cheap mower they will take pride in keeping the lawn in front well clipped and tidy. Besides this, if our native trees—Hickories, Oaks, Birches and Pines—are planted in groups, many interesting lessons in botany can be drawn from them by a skillful instructor. Flower-beds should be used with caution, but when children are properly interested they can be introduced to advantage, and it is certain that the influence of such a pleasant ground will do something toward improving and elevating taste and character.

In the discussion which followed it was objected that boys take the greatest delight in destroying everything that is planted in school-grounds. On the other hand, several members related their experience to prove that the interest of the children themselves can be enlisted, and then the danger of destruction is small. One speaker stated that he had planted the grounds of the school in his district three successive times, and the trees were always destroyed; but on the fourth occasion he invited the pupils to his nursery to dig up the trees for themselves. He accompanied them and directed the planting, which was also done by them with some little ceremony, including music, speaking and a pleasant collation. The result was that the whole school has entered heartily into the garden project, and has added flowers and shrubs, which they are watching with the utmost care.

The May frost, which did so much damage to fruit crops last year, did less injury to pears than to any other kind of fruit.

There never has been a glut in the market of first-class fruit. When carefully graded, the first quality always finds sale. It is the mixture of inferior fruit and fruit improperly prepared for market which brings down prices.

The area of land devoted to the cultivation of the Grape is rapidly increasing in Chautauqua County, and the so-called "Vineyard District," which extends for forty miles along the south-east shore of Lake Erie, will soon be entirely given up to this industry. Last year 360 acres were devoted to the propagation of the vine, and more than 10,000,000 cuttings were rooted.

Professor Caldwell, in speaking of the effect of fertilizers, cited an instance where wines of a particularly rich bouquet were made from grapes in a district whose soil was peculiarly rich in phosphate. A long treatment of phosphatic fertilizers was given by an experimenter to certain other lands where this element was less abundant, and, after thirty years, the peculiar bouquet appeared also in the wine produced from the latter district.

A letter was read from the venerable Lewis F. Allen, who is more than ninety years old and who settled in Buffalo when it was a village. Sixty years ago Plum-trees were found everywhere and were abundantly productive. Neither the curculio nor the Black Knot had then been heard of. Along the Canada shores of the Niagara River were Peach-trees ten inches in diameter and forty years old. The new-comers, encouraged by these indications, planted many Peach orchards on Grand Island and the neighboring shores, which were very profitable for a time. Thirty years later, however, the yellows came, and hardly a single tree is now living.

In the course of an address on the Fruit Evaporating industry, Mr. Michael Doyle gave some interesting facts concerning "chopped apples," a dried product from inferior fruit and material left after the preparation of the best quality of evaporated fruit. The export trade in this product had increased from small orders in 1880 to 11,000,000 pounds in 1888, and 20,000,000 pounds could have been sold in 1889. Cider was said to be a staple drink in northern France, and 276,000,000 gallons were consumed there annually. The chopped apples taken from here, and largely used for conversion into cider, are thoroughly dried, and are preferred to the home growth, being better preserved and of finer flavor. There now appears room for all we are able to export, although the Apple crop in France was valued last year at \$19,000,000—which seems like an enormous product for a single fruit.

In the report from Ontario County the following varieties—some of them new and some old ones which had not been generally planted in that region—were named as very desirable or promising: Of Apples, Longfield, Milding, Sutton's Beauty and Hubbardson's Nonesuch. Of Pears, Vermont Beauty is one of the very finest. Of Plums, French Damson, Field, Stanton, Prince of Wales, Middlebury, Peters' Yellow Gage—one of the very best of its color, The Czar—the best early, Diamond—a first-rate purple. Of sour Cherries, Montmorenci and English Morello. Of Early Peaches, Horton's Rivers, a seedling of Early Rivers, a most valuable introduction, and Hurd's Surprise. Of Apricots, a variety named Harris ripened in July. Of new Grapes, Geneva, a white seedling, seems worthy of trial. Of Currants, Fay, Moore's Ruby—the best flavored Cherry Currant yet produced. Of Blackberries, Early Barnard from Wisconsin the hardiest and best flavored.

Recent Plant Portraits.

Botanical Magazine, January:

HELIAMPHORA NUTANS, *t.* 7093; the remarkable South American representative of the North American Pitcher-plants, discovered half a century ago by the brothers Schomburgk in marshy savannahs near the base of Rossima, in British Guiana. It differs from the Sarracenias by its four to six parted perianth, three to five-flowered scape, uni-bracteal flowers, minute stigma, and by the small rudimentary lid of the pitchers. "Viewing their relations," Sir Joseph Hooker, the editor, remarks, "between these three genera to one another, the question naturally arises whether to regard *Heliamphora* as a degraded, or an ancestral member of the order. I incline to the latter view, though it points to the surmise that the order originated in a region now separated by upward of 2,000 miles from that inhabited by one of its other members in so far as their distribution is known." *Heliamphora* was rediscovered by the Orchid-collector, Burke, who brought plants to the Veitch Nursery in 1881. The illustration is from a plant which flowered at Chelsea in June of last year.

PLEUROTHALLIS ORNATA, *t.* 7094; a minute Mexican Orchid of botanical interest only.

PROTEA NANA, *t.* 7095.

ROSA BERBERIFOLIA, *t.* 7096; the simple-leaved Rose of Persia and western Turkestan, a charming species with small yellow flowers, and morphologically of the greatest interest on account of its peculiar leaves, whose stipules Dr. Masters has recently shown are suppressed, although potentially present; and therefore possibly to be developed in vigorous cultivated specimens. *Rosa berberifolia*, long considered difficult or impossible to cultivate, is now well established under glass at Kew.

IRIS BOISSIERI, *t.* 7097; a new bulbous species known only on a single mountain in Portugal. It belongs to the true Xipheons (the English and Spanish Irises of gardens), and its nearest relative is the Spanish *I. filifolia*. It differs, however, from its congeners in having a rudimentary band down the keel of the lower part of the outer segments, but for garden purposes it is hardly distinct enough in habit or in the form or coloring of the flowers to attract much attention.

SOBRALIA XANTHOLEUCA, *Revue Horticole*, January 1st.

Notes.

In Germany, young Spruces sold for Christmas-trees are often dusted over with fine shavings and a "brilliant" powder to imitate snow.

Small Ferns still occupy a prominent place in dinner-table arrangements, though the list of varieties used in quantity is quite short, *Adiantum cuneatum* as usual taking the lead.

An English correspondent notes with some satisfaction that the list of new Orchids for the year just past shows that the custom of giving hybrids Latin specific names is on the wane.

The Executive Committee of the Association of American Cemetery Superintendents have issued a circular calling upon the members to suggest at once desirable subjects for discussion at the meeting which is to be held in Boston next summer at the same time with the convention of the Society of American Florists.

The Pennsylvania Horticultural Society celebrated its sixty-first anniversary, on the 21st of January, by a large meeting of its members, together with many delegates from sister societies. Mr. George W. Childs, the newly elected President, took the chair for the first time in the hall that had been elabo-

ately decorated for the occasion. There was also an exhibition of remarkably rare and choice flowers.

The *Revue Horticole* calls attention to the fact that the name of the introducer of the Chrysanthemum into Europe is correctly written Pierre Blancard, and not Blanchard or Blanchart, as the name is sometimes written. Blancard was a sea-captain who made several voyages to Japan, and it was on his return from one of these voyages that he brought back to Europe the parents of many of the present race of cultivated Chrysanthemums.

The use of potted evergreens, such as *Retinosporas*, *Arbovitæ* and plants of similar character for house decoration, is on the increase, and some of our florists report ready sale for such plants in six and eight-inch pots. Many of these plants are lifted from the open ground in the fall and after being potted are placed in a cold house or frame until needed. They are useful decorations on account of their lasting qualities when exposed in draughty halls and similar locations, though they are too often arranged so as to give a rather formal effect.

M. André, in a recent issue of the *Revue Horticole*, mentions the fact that the finest specimen of the weeping *Sequoia gigantea*, one of the most interesting and remarkable of all conifers of abnormal growth; exists in the garden of M. Allard, at the Maulevrier, near Angers. It is about twenty-two feet high. The weeping *Sequoia* forms a slender, tapering column, the long pendent branches almost clinging to the main stem. This variety originated in France a few years ago, and among introductions of comparatively recent years no conifer showed at the Exposition in Paris last year created more admiration. M. Allard's collection of conifers, of Hollies and of Oaks, although not long established is one of the most interesting in Europe. It contains five specimens of the form of *Abies concolor*, peculiar to the mountains of Colorado, which cannot be equaled, perhaps, in Europe, in size, and particularly in the deep blue color of their foliage.

The meeting of the New York State Forestry Association, at Columbia College, on Saturday, February 1st, was called to order by Professor E. B. Southwick, the Secretary. Rev. Dr. Charles H. Hall, of Brooklyn, presided as temporary Chairman, until the arrival of General Egbert L. Viele, one of the Vice-Presidents. Hon. Warren Higley explained the object of the meeting. Letters from Hon. Seth Low, Edward M. Shepard and B. E. Fernow were read, and brief addresses were made by Judge Higley, Dr. Hall, Professor Daniel S. Martin, Dr. N. Jarchow, William Potts and J. B. Harrison. Mr. Morris K. Jesup, General Viele and Judge Higley were chosen as a committee to memorialize the Legislature in favor of efficient legislation for the preservation of the Adirondack Forests. General Viele, Professors Martin and Southwick, Mr. Potts and Mr. Harrison were appointed a committee to report to the next meeting amendments to the constitutions and nominations for permanent officers. The meeting adjourned to meet at three P. M. on Monday, February 10th, at Columbia College. The purpose is to complete the reorganization of the Association, and at once to enter upon active work for the promotion of suitable forestry legislation and the development of public interest in rational and practical methods of forest management.

The distinguished French botanist, Ernest Cosson, died in Paris on the last day of last year in his sixty-ninth year. Dr. Cosson published, in 1845, in connection with Germain de Saint Pierre, a classical and much esteemed *Flora* of the suburbs of Paris, of which three editions have appeared. M. Cosson was appointed, in 1851, Botanist to the Commission for the Exploration of the French Possessions in Africa; and the African flora has almost exclusively occupied his attention from that time until the day of his death. The seven years between 1852 and 1859 were largely devoted by him to examining in the field the vegetation of northern Africa, which he has since described in numerous important papers and memoirs. His great work, an illustrated *Flora* of Algeria, too long delayed by frequent arduous journeys in pursuit of additional information, remains, unfortunately, unfinished. M. Cosson was a man of independent means, which he devoted, like Bentham in England and the De Candolles and Boissier in Switzerland, to advancing the science of botany. His herbarium, unsurpassed in Algerian plants, was constantly enriched by acquisitions purchased from collectors in all parts of the world; while his botanical library had become one of the most valuable in the possession of an individual. This library and his herbarium M. Cosson placed always at the disposition of botanists, French and foreign, and many Americans remember with gratitude his kindness and the hospitality of his house in the Rue Boétie.

Forest Questions Before Congress.

ON January 20th President Harrison transmitted to the Senate and House of Representatives a memorial from the American Association for the Advancement of Science, relating to the preservation of forests upon the public domain, accompanying it with a message earnestly recommending that adequate legislation be provided to arrest the rapid and needless destruction of our great forest areas.

The memorial recalls the fact that the first national legislation which recognized the value of the country's forests and the necessity of throwing about them some protection, grew out of the presentation of the subject to Congress by a committee of this Association. This presentation led to the appointment, in 1877, of an agent, and later to the establishment of a Forestry Division in the Department of Agriculture, for the purpose of gathering and making accessible such information as might educate people to a proper conception of the value and significance of a forest-cover in the economic life of the nation. Twelve years have passed, and sufficient knowledge of our forest conditions, and of their helpful relation to cultural, climatic and economic conditions has been gained to demonstrate that further action by the general government is indispensable if these beneficent influences are to continue.

The Association, at its last meeting, resolved that immediate action ought to be taken for the establishment of a proper administration of the timber lands remaining in the hands of the governments of the United States and Canada, to insure the perpetuity of the forest-cover on the western mountain ranges, and this memorial is presented by a committee appointed under that resolution. It represents that the action asked for relates only to the forest-lands which are the property of the nation, and that the present administration of this property is plainly unsatisfactory, and must be speedily changed if far-reaching injury is to be prevented. It is insisted upon that the relations of the mountain forests to the agricultural regions in the plains are more important than the materials which they now furnish to settlers and miners, and it is urged that the Government alone can rightly administer this property. We

may add that in the enforcement of these positions it is sharply argued that a government which feels compelled to face the problem of irrigation for the agricultural development of part of its domain can hardly solve the water question without paying proper heed to the forest question.

In view of these facts the memorialists recommend the appointment of a joint committee of the two Houses of Congress, to consider the need of legislation for the public forest domain—legislation looking toward the appointment of a commission of competent men, salaried and employed for this service alone, to investigate the necessity of preserving certain parts of the present public forest-area, for the maintenance of favorable water conditions, and to devise a practical plan for the permanent administration of such parts of it as it shall appear desirable to retain under government control.

The memorial further recommends that pending such investigation all timber lands now owned by the United States be withdrawn from sale, and provision be made to protect these lands from theft and from ravages by fire, and to supply in a rational manner the local needs for wood and lumber, until a permanent system of forest-administration shall have been organized and put in operation.

The American Forestry Association has also presented a memorial to Congress, which admirably and concisely sets forth the need of action and the reasons for it. It points out that while the immediate withdrawal of the public forest-lands from sale and entry is absolutely essential, as a first step toward their preservation as forests, it will not of itself secure this end. The destructive fires and extensive thefts will go on as before. Still less will the mere reservation of these lands from sale enable the people to utilize the timber properly. The forest lands must be administered, protected from fire, and the timber cut only when ripe, and with a view to a constant new growth. Some portion of the army can be temporarily employed to guard these lands until a practical system of administration, a common-sense application of scientific knowledge, and of the results of the experience of other nations to the needs of the place and time, can be established. This memorial, a strong and temperate document, is accompanied by a bill providing for the withdrawal of the public forest-lands from survey, sale, entry or disposal under existing laws, and for the guardianship of the army over them while this temporary act remains in force. The bill also provides for the appointment of a Commission to examine the forest-lands of the public domain so as to determine what portions should be kept permanently in forest, and, on or before the opening of the second session of this Congress, to report full a plan for the proper management of the forest-lands belonging to the nation.

It is our belief that the statements in both these memorials are true, absolutely and beyond question, and that they do not exaggerate the evils which are sure to visit the country if the destruction of our forests is not speedily arrested. It is gratifying to know that these petitions are urged upon Congress by men of such attainment and position as Professors Mendenhall, Hilgard and Bessey, William Saunders, of Canada, and B. E. Fernow, who present the memorial of the American Association for the Advancement of Science; while that of the American Forestry Association is signed by Governor Beaver, Herbert Welsh and C. C. Binney, of Pennsylvania; Abbot Kinney, of California; Edgar T. Ensign, of Colorado; and Judge Higley, of New York. The President of the United States, in his message, has followed the example of more than one of his predecessors in recommending prompt action in this matter, and it remains to be seen whether Congress will listen to these entreaties. France has no surplus to expend for any public improvement which does not yield positive and tangible benefit, but France has spent \$50,000,000 already to cure the ruin wrought by deforestation, and will spend as much more. Italy is poor, but she is appropri-

ating money to re-clothe a million acres of land which has been stripped of forests. Austria has 800 torrents to hold in check, and Prussia every year buys up waste lands for the purpose of reforesting them. What thoughtful men in this country are asking is not the outlay of millions, but the use of ordinary foresight to make such outlay unnecessary. They only ask that the most efficient agents of forest destruction be restrained for a season, until some persons who are competent can tell us what we really have, and how much of that must be preserved to save us from remediless disaster. A refusal on the part of Congress to give heed to this appeal, which is repeated year after year with increasing earnestness and urgency, would be little less than criminal.

The portrait of a remarkable Walnut-tree found growing by Professor Rothrock at Lower Brandon, on the lower James River, in Virginia, is published in the January issue of *Forest Leaves*. Professor Rothrock describes it as "a gigantic spreading tree, which towers higher and spreads over a wider area than any of its associates. This is always plainly visible, but particularly so when winter has stripped the leaves and allowed the branches to stand out on the background of a cold sky." No one knows when the tree was planted, and nothing is known of its origin. The remarkable thing about it is, that in bark and in foliage this tree is almost identical with common forms of the so-called English Walnut (*Juglans regia*), while the nuts, which have a thick, rough and deeply furrowed endocarp or shell, and thick cell-walls, are not distinguishable from some forms of the nut of the Black Walnut; and the tree thus presents every appearance of being a hybrid between the American and the old-world Walnuts. The Walnut-tree cut last year on the grounds of the late Ben Perley Poor, near Newburyport, Massachusetts, mentioned on page 14 of vol. ii. of this journal, had the same peculiarities as the James River tree, and one of the stories told about the Newburyport Walnut was that it came originally from Virginia. There is another specimen of the same tree growing in the grounds of the Episcopal School of Harvard University, in Cambridge, of whose origin no one knows anything. The presence of American blood in these trees is shown not only in the nut, but in the fact that the Newburyport tree and the Cambridge tree are both perfectly hardy, and have grown to a large size, while the English Walnut in Massachusetts is precariously hardy, and, when it grows at all, never attains to any great size. We hope to publish a figure of the foliage and fruit of this interesting tree, but before doing so it is desirable to obtain as much information of its origin and of other individuals which may be growing in Virginia as it is possible to acquire. It is in the hope that some of our readers may be able to throw some further light upon the subject that this preliminary note is now printed.

Entrance to the Père-Lachaise Cemetery, Paris.

THERE are nineteen cemeteries in Paris, thirteen in the city proper and six in the suburbs. In the former the ground is granted in perpetuity, in the latter for a stipulated period only. The largest and most famous of all is the Eastern Cemetery, more commonly called "Père-Lachaise." It is not so ancient as is usually believed, having been laid out in 1804 under the direction of the architect Brogniart. The principal entrance, shown in our illustration on page 79, is a model of what such a construction should be—dignified, yet not obtrusive or showy, appropriately massive and severe, yet not gloomy-looking, and expressing its function in the emblems chosen for its decoration as well as in its general effect. According to French writers the aspect of the cemetery itself "is not in the least lugubrious," and they are certainly right in saying that the "majority of visitors consider it rather a promenade than a funereal spot." Nevertheless, to trans-Atlantic eyes it seems lugubrious enough by contrast with the open, park-like and cheerful look of even those American cemeteries which we think most sadly overcrowded. As can be divined from our picture, its alleys are thickly lined with tombs, many of them large and very ornate, and, though trees

grow in abundance, there is little room for grass and none for the attainment of those open landscape effects which Americans think most desirable in a cemetery. Near the entrance the wall includes but a small space on the right hand, encumbered by various official buildings. But a little further on it bends sharply to the right and the corner thus formed is the Hebrew portion of the burial-ground. From the entrance there is a considerable ascent to a point occupied by the chapel, and thence the hill slopes toward the east and the newer part of the enclosure. This part is laid out in rectangular divisions, but in the older portions the alleys are winding, and, as they meet, form various open spots which relieve the general monotony of close-grouped memorials.

The Art of Gardening—An Historical Sketch. XVII.—Ancient India.

THE luxuriant imagination of the ancient Hindu expressed itself in architectural forms which, while they lacked the purity of Greek and the intellectual suggestion of mediæval European types, have a brilliant, gorgeous beauty that harmonizes well with their semi-tropical surroundings. None of the Hindu remains antedate the time when stone replaced wood as the material of construction, and this seems not to have been earlier than the third century, B. C. But tastes and customs are peculiarly persistent in the East, and from their witness we can understand the rôle that gardening played in India in very ancient times.*

The simplest type of an old Indian garden was the enclosed court intimately connected with temple or habitation. The great Buddhist monasteries, where thousands of persons sometimes dwelt, were composed of an immense number of apartments surrounding open courts, and remains of their groves and huge water-basins may still be traced. A plan of a temple at Ramisseram, in the south of India, published by Fergusson,† shows a succession of enormous colonnades, 700 feet in length, encircling the main buildings and encircled themselves on two sides by a wide expanse of formally planted garden, all together being surrounded by a wall twenty feet in height. And everywhere we read of temple-enclosures filled with smaller temples, tanks, garden-plots, colonnades and fountains.

In such places as these the gardens were features in a great architectural whole; but there are others where the buildings were but features in the landscape. Here again, however, a true regard was paid to unity of effect. In no country, it may be said with especial emphasis, has the art of combining architectural forms with sheets of water been so perfectly understood. Both the value of the mere cool aspect of water in so hot a climate and the custom of frequent ablutions made it desirable that many buildings should stand near every lake and stream. Here temples, colonnades, terraces, kiosks and wide stairways for bathing purposes are harmoniously grouped together and beautifully composed against backgrounds of thick groves or sloping hill-sides. One of the palaces of Chittore, writes Fergusson (which were built in the fifteenth century, but by a prince of one of the old dynasties, and may be accepted, therefore, as representing an art of far earlier origin), "stands on the verge of an extensive lake surrounded by hills of great beauty of outline; and in the lake are two island palaces . . . which are more beautiful of their class than any I know elsewhere. It would be difficult to find any scene where art and nature are so happily blended together and produce so fairy-like an effect." Studying the pictures of Chittore and of many similar places, we realize that chance—the mere accident of a beautiful natural landscape—had little to do with the charm of the general result. Temple and palace were not left in isolation amid untouched natural surroundings. Platforms, terraces, stairways, walls and gateways formed the transition from one to the other; each adjunct was considered not only for its intrinsic beauty, but for its value as a feature in the general picture, and prospect as well as aspect was considered. The great palace at Oodeypur, for example, which lies in a district not overrun by Mahometan influence, "covers the entire crest of a hill, the base of which is washed by the blue waters of Lake Peshola; and this crest being insufficient for the full consummation of the architect's design, an immense terrace had been carried out on a level with it, and supported by three massive tiers of arched vaults."‡ The palace, as usual, consists of a multitude of different buildings and court-yards, and the whole is so arranged as to resemble "a vast

* There are no books to help out the witness of art. Indian literature, so very rich in many directions, includes no historical works.

† "History of Indian and Eastern Architecture."

‡ "India, Pictorial and Descriptive."

hanging garden. . . . A sparkling fountain is the central point from which avenues paved with white marble radiate in all directions, and rills of shining water flow in narrow channels until lost in the shade of Orange and Pomegranate-trees. . . . A marble gallery encircles this enchanting spot," whence the view embraces the whole valley; and "terraced gardens, crowded with summer-houses, pavilions and fountains, lead down to the lake, the shores of which are lined with fairy-like structures. . . . The arched roof of one of these . . . rests on a thousand slender columns, and all around it is woven a woof of shimmering, rainbow-tinted mist by the leaping waters of numerous fountains."

Formal flower-beds have always been a conspicuous feature in Hindu gardening, and have shown that keen sense for harmony as well as brilliancy in tint which distinguishes the race in all its artistic endeavors. Indeed, dwellers in a northern clime can hardly picture the gorgeous beauty of Indian color, produced by a combination of architectural and natural elements under the vivid blue of a southern sky.

Communication between China and India always existed to a certain extent; but the general trend of influence was eastward, not westward. The Chinese got much from the Hindus, but how much these may have received in return is far harder to decide. On the other hand, we know that ancient India was vitally affected by Persian ideas. The old Achemenid dynasty ruled to the Indus or beyond; Alexander's expedition influenced at least the outskirts of the peninsula; and the later Bactrian, Parthian, Seleucid and Sassanid dynasties followed up the work. Many elements of Persian origin can be found in Hindu architecture, and, as architecture has been affected, so has also been, in all parts of the world, the art of gardening. When Quintus Curtius writes of an Indian king it sounds like a description of some royal Persian: "His principal existence is hunting; amidst the vows and songs of his concubines he shoots animals which have been confined in a park."

On the whole, however, a distinctly national taste was doubtless expressed in the gardens of ancient India, for, despite all their borrowed details, such was the case with its buildings. The strong feeling for the picturesque and fantastic which is revealed by Hindu architecture as well as poetry had no parallel, as far as we can discern, in Persia. It speaks rather of the further East, finding its consummate expression in the gardens of the Flowery Kingdom. It is strongly illustrated in one or two pictures published by Fergusson. In some Indian districts the temples are not built, but excavated—dug bodily out of the solid rock of hill-sides. And here, at times, the approach is not by means of artificial steps and terraces, but between great boulders and free-growing trees, the effect of which is very like those "natural" arrangements which are typical of China and Japan. *M. G. Van Rensselaer.*

New York City.

Exotic Shrubs in Canada.

FRUIT-GROWING and the testing of the hardiness of fruit-trees and shrubs have received a good deal of attention in the Province of Quebec and in some parts of the lower provinces of Canada, but comparatively few trials have been made of the hardiness and value of many other trees and shrubs not indigenous, but which might prove useful and ornamental. In some old gardens about Montreal it is not unusual to find specimens of shrubby or arborescent plants which have been brought over from Europe; but, as many of these were imported from the south of England or other stations almost equally mild, instead of from the most northern countries possible, they are too often poor specimens, and unsatisfactory on account of lack of hardiness.

Few persons have experimented with any considerable number of species, but the recently organized agricultural experiment-stations of the Dominion and the proposed botanic garden at Montreal give reason to hope for some systematic experiments and reliable data in the near future. The winters at Montreal are not so severe as many people suppose, and an examination of isothermal charts and of Dr. Robert Bell's map giving the general northern limits of the principal trees of the Dominion shows this clearly. Nevertheless, when compared with the climate of eastern Massachusetts that of Montreal seems quite severe—severe enough to prevent many plants from flourishing which do admirably in the Northern States.

Three years ago a box of small specimens of some foreign trees and shrubs were sent from the Arnold Arboretum to a garden on the south side of the St. Lawrence River, opposite to and within ten miles of Montreal. Some of these plants died soon after they were received and

planted, because the season was an exceedingly unfavorable one for plants not already well established; and all those belonging to the Heath family were lost during the first year on account of the lime in the soil, a limestone region or calcareous soil being fatal to all, or almost all, the *Ericaceæ*.

An examination of the surviving plants a few weeks ago furnished some interesting comparisons with the behavior of the same species in the Arboretum at Boston.

A most interesting example is afforded by the small plants of the rare Yellow-wood (*Cladrastis lutea*) of Kentucky and Tennessee, which appears to grow freely and ripen its wood, and seems perfectly hardy in a most exposed situation without any natural or artificial protection. It promises to be a valuable addition to the small ornamental trees at the north. Attempts have often been made to introduce the beautiful Laburnum from European gardens, but so far without even the poor success which it sometimes obtains at Boston. It is almost invariably winter-killed to the ground.

The appearance of *Cercidiphyllum japonicum*, still so rare in cultivation, gives much promise that it will be of ornamental value and interest at the north. Although the ends of some of the branches seem to have suffered in winter, the little plant sent from the Arboretum is now eight or nine feet high. The seed of this inconspicuous-flowered representative of the Magnolia family came from one of the northern islands of Japan, and the hardiness of the plant so far north in this country leads to the hope that *Magnolia Kobus*, from the same region, as well as other untried northern-Japanese plants, may be able to withstand the winters north of latitude forty-five.

The Japanese *Acer polymorphum*, when not overfed or grown too fast, seems about as hardy as at Boston, where, as a rule, it is not very satisfactory, although always interesting.

The valuable collections of seeds made by Dr. E. Bretschneider in the mountains about Pekin, China, have already been referred to in GARDEN AND FOREST, and among these were stones of a Peach which he found growing wild. The plants in the Arboretum raised from some of these seeds have thrived and fruited, and a grafted plant sent to this Canadian garden now forms a good sized bush, and has not yet shown any injury from the severity of the climate. The fruit of these Chinese seedlings is white, medium-sized, poor in flavor and has a large stone; but if the plant proves hardy it will be a valuable acquisition and a good stock upon which to begin improvements. The Peach has not been grown in the open air at Montreal except in rare cases, where it has been trained to a wall and well covered in winter.

The common Quince is not successfully grown in the climate of Montreal, and this is also true of the Japan Quince (*Pyrus Japonica*), which has so far not proved as hardy and beautiful as at Boston. The plants live, but are prostrate in habit because usually badly killed in winter. They may thrive in some favored situations, as excessive moisture and late continued growth are very often the destroyers of shrubs which under opposite conditions seem hardy.

Rosa blanda is the common native wild Rose of the region under consideration, and, of various foreign species of Roses tried, none have proved so hardy and thoroughly reliable as *Rosa rugosa* and its white variety. The plants attain as large size as they do in southern New England, and they retain the habit of producing a few flowers throughout the summer and autumn after the regular season of profuse blooming. Near Montreal they have grown for at least ten years without showing the slightest injury by winter cold, and they seem hardy enough to grow in Labrador. Indeed, they are reported as perfectly hardy at St. Petersburg, which, having a winter climate which averages but little colder than that of Montreal, although with greater extremes, is situated in the latitude of sixty degrees, corresponding to the northern shores of Labrador or the southern extremity of Greenland. The red foliage of *Rosa rubrifolia* makes this species attractive and interesting to many people, and it has proved hardy.

Rosa multiflora, of Thunberg, has sometimes had part of its branches killed, but is sufficiently hardy to bear an abundance of blossoms every season. In some situations it would probably be uninjured even so far north.

The Sweetbrier Rose (*R. rubiginosa*) must have been introduced to the vicinity of Montreal many years ago, as it has escaped from cultivation and is growing quite commonly and vigorously in some pastures. The pretty Japanese *Spiraea Thunbergii* appears to be quite hardy, and is a valuable addition to the shrubs. Some other foreign species of *Spiraea* do well, especially those which are natives of comparatively high latitudes.

The Caraganas from Russia and from Siberia are naturally perfectly hardy. *Caragana arborescens* and *C. frutescens* be-

come quite large shrubs, and, when laden with their yellow Pea-like blossoms, are quite ornamental, being, perhaps, the best yellow flowered shrubs to use as substitutes for the desired Laburnum.

Deutzia gracilis, being of dwarf habit, is usually well protected by snow, and rarely fails to blossom as well as at the Arboretum; but the large growing *Deutzia scabra* (also found in catalogues as *D. crenata*, *D. Japonica* and *D. Sieboldiana*), although it usually bears some flowers, is very liable to have its shoots killed in winter to within a foot or two from the surface of the ground. This also occurs about Boston, if the plants are situated in low or very moist ground, where growth is prolonged and the wood does not fully ripen before winter. In favored situations at the north it may prove quite hardy.

The common varieties of Mock Orange (*Philadelphus*) and the Tartarian Honeysuckles grow as luxuriantly as they do several hundred miles further south, and the Dutch Honeysuckle (*L. Periclymenum*) blooms freely every year if lowered from its trellis to the ground in the autumn and given a slight winter covering of leaves or branches where the snow does not remain.

The great-flowered form of *Hydrangea paniculata* does very well where the soil is not too wet and it is not forced to too vigorous growth; and some varieties of Weigela (*Diervilla*) are moderately hardy when grown under the same conditions.

Forsythia viridissima seems to do best when given a slight protection in winter—pegging to the ground being sufficient where it is covered by snow.

The Holly-leaved Mahonia (*Berberis Aquifolium*) is as badly winter killed as it is about Boston, and needs much protection from sudden changes of temperature in winter and from the consequent freezings and thawings. Plants of *Tamarix tetrandra* seem quite hardy, and have flowered freely though still small. Its hardiness is to be expected, as it is said to be a native of high latitudes and altitudes.

Most of the shrubs mentioned have received only partial protection from the snows of winter, and they have stood from twenty to twenty-five degrees below zero when there was very little or no snow on the ground.

Some of the smaller shrubs, such as the Flowering Almond, Woad-wax (*Genista tinctoria*), *Cytisus purpureus*, *C. nigricans*, *Euonymus nanus*, *Vinca minor*, etc., receiving more natural protection than the taller species, are hardy and satisfactory. Doubtless some seemingly half-hardy species may be grown in sheltered gardens of cities like Montreal and Quebec; but, in exposed places, soil and situation are as important as difference of degrees of latitude, and well drained ground and slow growth, leading to thorough ripening of wood, are the greatest protections many trees and shrubs require.

J. G. F.

Arnold Arboretum.

Vanda cœrulea.

THIS Vanda is undoubtedly the handsomest of the comparatively few blue-flowered Orchids. In former years it was rarely grown in such thrifty condition as it is now met with, and the failures with it were chiefly due to the great heat to which the plants were subjected. Coming from the Khasya Hills, where it is found at an altitude of from 3,000 to 4,000 feet, it naturally requires little heat and delights in a free circulation of air. The illustration on page 77 is from a photograph of a fine specimen in the collection of Mr. Hicks Arnold, of this city. It is in superb health, two feet high, and furnished to the bottom with perfect leaves. Last autumn it bore, on four spikes, fifty well developed flowers of a clear, azure blue color. The plant has been in Mr. Arnold's collection for two years, and has grown very rapidly. It is placed where it receives plenty of light and air, and that it thoroughly enjoys the position may be inferred from the numerous roots that show themselves outside the basket.

Foreign Correspondence.

London Letter.

THE enormous demand for flowers in winter in England is taken advantage of by foreigners in the same way as is the demand for fruits and similar commodities. In Italy, southern France, Spain, and even Algeria, the production of flowers for the English and other northern markets during winter has lately become an important industry. Besides these there are also large flower-farms in the Scilly Islands, where Grapes, Pears, early Potatoes and vegetables are largely grown solely for English consumption. The development of

the flower-farms in these islands is the subject of an interesting communication to the *Gardeners' Chronicle* by Mr. W. Roberts. When ordinary farming proved a poor business, market-gardening was tried, but it was not until about ten years ago that the cultivation of flowers for exportation was commenced in earnest. Enormous quantities of the flowers of Freesias, Anemones, Wallflowers, Roses and Persian Ranunculuses are now sent from these islands to England, and to the uninitiated are the cause of much wonder when seen on every stall and in every flower-dealer's window in February and March. But the flowers which are grown in greatest abundance, which find the readiest market, and which prove most profitable to the growers, are the Narcissi. Every available bit of ground is planted with the bulbs of these plants in various kinds, and from November right on to May they are the glory of the islands. The bulbs are planted from two to four inches deep and six inches apart; they are not matured, except by the decay of their own leaves. They are dug up, divided and replanted about every three years. It is supposed that \$1,250,000 is now invested by the Scillonians in these plants alone. Some 15,000 boxes of flowers of Narcissi are sent to England from these islands every year, as many as 500,000 spikes having been sent by one man in a single consignment. The spikes are tied in bundles of twelve and packed neatly in boxes. It is stated that during the winter season from ten to fifteen tons of cut flowers are sent to the English market from the Scilly Islands in a single day. By taking advantage of the English demand for flowers, and supplying such as carry and keep well, and which are popular, the inhabitants of these islands have shown how such a slight advantage as they possess in regard to climate, when compared with England, may be turned to the very best account. The market value of the flowers of these Narcissi varies from three pence to three shillings per bunch of twelve.

The following plants are now flowering freely at Kew in an unheated greenhouse, where early flowering tender alpine and herbaceous plants are accommodated. A house of this kind may easily be made one of the most charming features of the in-door garden during winter and spring. Hellebores, both of the Niger and Orientalis (or Lent Lily) sections, are abundantly represented by large masses crowded with flowers. *Hepatica triloba*, in white, purple and blue forms, two or even more colors sometimes occurring on the same plant, is conspicuous. *Milla uniflora* is a tuft of rich green leaves and numerous milk-white, star-shaped flowers. *Primula Fortunei* is the rarest and most interesting of the Primroses now in flower; it is in the way of *P. denticulata*, but has looser heads of lavender, yellow-eyed flowers. *P. obconica* is grown in quantity. The poisonous properties attributed to this species have never been experienced at Kew. Crocuses of many kinds and *Narcissus minimus*, with its delightful little trumpets, are other plants which now help to make this house one of the chief attractions at Kew.

ORCHIDS.—Public auction sales of these plants do not appear to be nearly so remunerative now as they were about twelve years ago, when those engaged in the work of collecting and importing Orchids were so few as to be able to practically control the market. Where there was one importer of Orchids in those days there are perhaps twenty now, and the consequence is that many of them find difficulty in getting their plants sold at anything like remunerative prices. In the early days, when Stevens, of Covent Garden, was the only auctioneer of Orchids, and when Low, Bull, and latterly Sander, were the only importers, it was nothing unusual for the whole expense of collecting and bringing to England a quantity of Orchids, with a handsome profit besides, to be realized at the first public sale. Then such prices as ten, twenty, fifty, and even one hundred guineas for a single specimen were not unusual. The game paid too well for it to long remain in the hands of a few, and now there are so many importers that a considerable proportion of them can scarcely make Orchid-importing pay. Although the cost of collecting and transporting these plants from distant lands is not now so great as it was a few years ago, yet an expedition to such countries as upper Burmah, Madagascar, New Guinea, or even to some parts of South America, requires an outlay of some hundreds of pounds, not to reckon the risks to the health and even to the lives of the collectors, before a quantity of plants are landed safely in England. Even then it is not an uncommon occurrence for nearly all of the plants to be dead on arrival or too sick to recover. Only this week I have learned of a case of this kind. A well known and very successful importer informed me that a lot of Orchids from Central America, which recently arrived in good condition, was the third attempt to get these plants home alive, two previous attempts having proved complete failures,

Fig. 17.—*Vanda coerulea*.—See page 76.

although each one was as expensive as the last. And now comes the disheartening part. These plants, obtained at such an outlay, when placed in the market have not realized anything like the sum spent in collecting and importing them, apart altogether from losses on the other attempts. Another similar case is that of Mr. Wallace, of Colchester, who has just returned from collecting in tropical west Africa, and has succeeded in bringing to England about sixty plants of an *Angræcum* new to cultivation, and a very fine thing. These sixty plants are all that survived of some thousands collected. In the auction rooms the prices these rare Orchids brought were absurdly low; I do not think they would more than pay the cost of packing and freight. Again, it sometimes happens that on the eve of a sale of an importation of Orchids information of a second, or even third, importation is made public. People who are astonished at the exceptional value of an Orchid, do not take into consideration the difficulties and cost of bringing the plants to England. Many of them are as rare and as difficult to get at as diamonds.

Angræcum pallidum.—This is the Orchid which Mr. Wallace, of Colchester, has just brought from the west coast of Africa and offered for sale at the auction-rooms this week. It has fleshy, strap-shaped, distichous leaves nearly two feet long, two and a half inches wide in the broadest part and shining green, and is in the way of, but larger than, *A. pellucidum*. The flowers are produced on thin spikes two feet or more long, some of the imported plants showing no less than thirty dried spikes; each spike bears about sixty flowers, which are creamy white, almost transparent, apparently about as large as those of *A. Sanderianum*. In bloom the plants are said to present a grand appearance. Judging by the imported plants, I should say that *A. pallidum* is a gigantic *A. hyaloides*, which is peculiar amongst cultivated *Angræcums* in producing erect spikes of white flowers in great profusion from the base of the plant. If *A. pallidum* proves amenable to ordinary stove treatment—and there is no reason to doubt that it will do so, since the other tropical African *Angræcums* are easy to cultivate—it will be a valuable addition to the already numerous species of this genus now in cultivation.

Maxillaria Sanderiana.—Hitherto this plant has been very rare, only one or two growers having saved plants of an importation of Mr. Sander's some six years ago. Probably excessive heat caused the death of most of the plants, the general belief being that this species required tropical treatment. It is happiest in an intermediate house, or say, along with Cattleyas. Messrs. Shuttleworth, Cardes & Co., of Clapham, have just succeeded in importing a good lot of this species, so that it should henceforth be as popular as other *Maxillarias*. It is one of the very best of the genus, having flowers as large and of as much substance as those of *Lycaste Skinneri*; they are five inches across, pure white, the lip and lower part of the segments deep crimson. The species is a native of Peru.

Cypripedium Godefroyæ.—When first introduced some seven years ago this pretty little species found many purchasers at from five to ten guineas a plant. This week I saw it sold at the auction rooms, newly imported plants in fine condition, at from three pence to six pence per plant. Most growers prefer the newer and handsomer *C. bellatulum*, a near relative if not actually a variety of the former. In England it is not easy to keep these and other *Cypripediums* of this section in good health during the winter; they are singular in the genus in their love of bright sunshine, of which we have, as a rule, very little in winter—at any rate, in the near neighborhood of London. The natural conditions for *C. Godefroyæ* are "on the cliffs of a limestone island, where, after about ten o'clock A. M., they are exposed till sunset to the full glare of a tropical sun."

Cultural Department.

Ericas.

THE Cape Heaths have always held a prominent position among greenhouse flowering plants in England. They were much more popular in the early part of this century than they are now, although a select few of the easiest to manage and with showy flowers are still grown in immense numbers, especially in the neighborhood of London. There are also still a few private gardens where a good representative collection of *Ericas* is cultivated.

The genus is said to comprise some 400 species. Of this number no less than seven-eighths are found in the southwestern region of the Cape. This region is an angular littoral strip, extending from Port Elizabeth to Oliphants' River and

with an average width of fifty miles. Nearly all the best of garden plants from south Africa are found here. The showiest of the *Ericas* are, according to Bolus, found on the mountains; *E. cerinthoides*, *E. mammosa*, *E. coccinea*, *E. spumosa* and *E. hirta* being the most abundant; the last named making whole mountain-sides glow with its warm pink-colored flowers. In England a similar effect is produced by the rich glowing purple of our native Heather, which covers miles of moor and hill-side.

According to Aiton there were close upon 200 species of Cape *Ericas* in cultivation here in 1810; about half of this number having been sent home by Francis Masson, who collected at the Cape for Kew. Loudon, in the "*Hortus Britannicus*," enumerates no less than 565 species, so called, as having been cultivated in England, 348 of which were figured in the *Botanical Magazine*, Andrews' "Heathery" and other works. The position in horticulture held at that time by these plants was evidently an exceptional one.

The art of cultivating Cape Heaths appears to have been acquired in England almost from the date of their first introduction. Specimen plants six feet through and as many high, in splendid health and full of bloom, were common features at plant exhibitions forty or fifty years ago, and now and again such specimens are to be seen in English collections to-day. Whether some peculiarity of climate or other conditions favors the growth of these plants in England and Scotland, it would be difficult to say, but certainly in no other country, not even at the Cape itself, are such specimens of *Ericas* to be seen as are produced by cultivation in England. The principal introducers and dealers in Cape Heaths in England were, after Kew, Messrs. Lee & Kennedy, Low, Rollisson, and Fraser. In addition to the species, a large number of hybrids and seedling varieties were raised in England, chiefly by Rollisson, Turnbull, Marnock and the McNabs. Many of these eventually superseded the species, and to-day one may safely say that of the *Ericas* represented in English gardens considerably more than half are hybrids of garden origin. It has been computed that of species, hybrids and varieties something like one thousand kinds of *Erica* have been known and grown here.

The Kew collection of these plants contains probably every one of the true species in cultivation in England and a good number of the hybrids and varieties. Altogether they number 142.

The beautiful colors, elegance of form and other charms of many species of Cape *Ericas* are, to some extent, depicted in the large edition of Andrews' "Heathery." These drawings, however, beautiful though they are, fail to convey any idea of the ornamental character of well grown specimens when well flowered. Such kinds as those mentioned at the end of this paper have very few equals among greenhouse flowering plants. *Ericas*, when properly treated, flower very freely, and their blooms remain fresh a long time, either when cut or when left on the plants. Many of them flower at a time when they are of exceptional value. No well furnished conservatory in winter can fail to show plants of such kinds as *E. hyemalis*, *E. colorans*, *E. hybrida* and *E. persoluta*. By selecting the plants according to their flowering season, one might easily have a few examples in flower at all times in the year.

The cultivation of Cape Heaths is not nearly so difficult as is popularly supposed. Where their requirements are properly understood they are grown by the thousand, by men of the rank of garden laborers. They are all what are here termed cool greenhouse plants, requiring a minimum temperature a few degrees above freezing point, and during hot weather exposure to full sunshine in the open. When under glass they must have an abundant and regular supply of fresh air; the atmosphere also should be kept as dry as possible. They thrive only when planted in good rich peat, made very porous by adding plenty of sharp silver sand. The pots should be well drained, and the soil made as firm as possible with the hand. Potting sticks, unless very carefully used, are often the source of much injury. The time to repot is from January to March. Free-growing kinds, such as *E. hyemalis*, may be shifted annually into pots two or three sizes larger than those they are in; but the slow-growing, hard wooded kinds do not require more than one size larger each year. From the mistaken belief that when a Heath dies it is the result of over-watering, beginners often err by keeping their plants too dry. When in good health *Ericas* require as much moisture at the root as most plants; but the soil must be kept sweet and never allowed to become water-logged. Avoid extremes in regard to watering and *Ericas* have what they require. During summer the free-growing kinds should be watered occasionally with weak manure water.

Ericas often grow leggy and thin because they have not been cut back or stopped sufficiently. The hard-wooded kinds should have the points of their strongest shoots removed soon after the flowers are over and growth has started again; the soft-wooded kinds should be cut back hard a few weeks before they are repotted, and kept a little warmer until they break. Mildew is the greatest enemy of these plants; it may be kept under by means of sulphur. Prevention is, however, better than cure, and if the plants are well supplied with fresh dry air they will not suffer much from mildew.

A selection of the best of the Ericas now known in gardens would include the following:

Soft-wooded.—*E. Caffra*, *E. Cavendishiana*, *E. cerinthoides*, *E. colorans*, *E. Eweriana*, *E. gracilis*, *E. grandinosa*, *E. hybrida*, *E. hyemalis*, *E. melanthera*, *E. perspicua*, *E. persoluta*, *E. ventricosa*, vars., and *E. Wilmoreana*.

Hard-wooded.—*E. Aitoniana*, *E. ampullacea*, vars., *E. Devoniana*, *E. effusa*, *E. eximea*, *E. Fairieana*, *E. Jacksoniana*, *E. jasminiflora*, *E. Kingstonsiensis*, *E. McNabiana*, *E. Mas-*

stem three feet in height it is certain to be dead on the south side of the stem in three years. But top-worked on the Asiatic species (*Elæagnus angustifolia*), even at a height of six feet its stem will remain perfect. Of this we have examples, in many directions. In fruits some varieties fail in stem which are perfect in top. In such cases top-working on stocks that are proof against sun and wind is an evident advantage.

Top-working is an advantage in another way on our extremely varied soils. As an instance, the Gros Pomier Apple does remarkably well on sandy land where many sorts utterly fail. Working the sorts that fail on sand on this stock seems to meet with success.

Again, the Tetofsky Apple does well on low, wet prairie land where most other sorts fail, and experience has shown an advantage in using it as a stock on such soils. In Silesia this adaptation of fruit-tree stocks to varied soils has reached greater perfection than in any country of which I have information.

soni, *E. Marnockiana*, *E. ovata*, *E. retorta*, *E. Shannoniana*, *E. tricolor*, vars., *E. vestita*, and *E. Victoria-Reginæ*.

These would form a good collection to begin with. Probably a hundred kinds, all first-class flowering plants for the greenhouse, could be got together even now, for there are still a few nurserymen in England who grow a good collection of Cape Heaths.

Kew.

W.

Grafting.—There is no proof that a tree which is liable to injury in our trying climate can be made hardier by grafting it on an iron-clad stock, but top-working is of advantage in more than one way. In our interior climate, trees doing well under forest conditions as to shade of stem may utterly fail when the stems are exposed to the direct rays of the sun and hot south-west winds when isolated on the open prairie. As an instance, the Buffalo berry (*Shepherdia argentea*) is plentiful on the banks of the upper Missouri, growing thickly like Hazel brush; but when planted by itself in our yards with a

Perennial Pyrethrums.—There are few hardy plants that have lent themselves so kindly to the skillful manipulation of the florist and been so obviously improved thereby as the parent of this useful race of hardy plants, *Pyrethrum roseum*. Indeed it is a mystery how, from this, the original species, a pretty thing in itself, much resembling a rose-colored Ox-eye Daisy, such beautiful varieties have been obtained, notably the one with large, double white flowers with not a tinge of color to mar their snowy purity and others of the brightest crimson and all the various shades between the two. Their cultivation is extremely simple, as it is only necessary to plant them in good soil well enriched and leave them alone, to become possessed of fine strong clumps, and it is from these that good and satisfactory results may be anticipated. The flowering period of these Pyrethrums extends over the whole of the summer season, and this is a trait worthy of special notice when one considers the durability of the flowers in a cut state. When it is desired to increase the stock of plants none but strong clumps should be selected for this purpose, and the

operation is best performed in spring, as early as possible, when the plants may be taken up, care being taken to secure roots to each portion of the plant. These may then be replanted and the operation will prove beneficial if carefully performed. Pyrethrums may also be easily raised from seed if it is fresh and of a good strain, such as sent out by the large European seed-growers. All of the plants will not produce double flowers, still the single ones are exceedingly pretty and useful, and indeed some growers are making a specialty of single varieties. Some of the older double varieties named below are still as good as any that can be found either in catalogues or gardens. The two best white varieties are Mount Blanc and White Aster, while Captain Nares, Emilie Lemoine and Progress are among the best reds, and Ne plus ultra, Iveryana, Dr. Livingstone and La Vestal are all good shades of pink and lilac; J. N. Swerdy is a brilliant red and good. All of these we have grown and find them as good as the best. Each year adds new kinds to the already long list.

Passaic, N. J.

O.

Perennials from Seed.—III.

AFTER the seeds have germinated and are large enough to handle—that is, when there are at least two fully developed leaves besides the seed-leaves—the time has arrived for transplanting or pricking out into boxes or pots. This is a critical period in the life of the plant, and inattention then often results in a weak or spindly growth, which necessitates weeks of nursing and care to strengthen and enable it to stand the hot sun sufficiently to bear planting out permanently. This is especially true when, as sometimes happens, the seeds come up thickly in the pan. If the rougher portion of the soil has been used as drainage to the seed-pan, the young plants can be separated easily without injury to a single root, but when moss or leaves are used there is great difficulty in disentangling the roots, and the young seedlings receive a severe check. Three-inch pots are the most suitable size if the plants are, of strong, robust habit, such as Delphinium, Coreopsis, Hollyhock, Papaver and Lathyrus. In pots of this size the young plants will grow strong and form a mass of roots that will defy any period of dry weather that may ensue if they are well watered before planting. The best soil is two-thirds good loam and one-third leaf-mould. Should the plants be naturally tender-rooted, it is best to place them at the side of the pot instead of in the centre, for the young roots love to feel the side of the pot, and when they find the way around it is the time when the plant seems to enjoy life the most. For all small, dwarf-growing plants of alpine character two-inch pots are large enough. After potting, the young plants will need careful watering, although water should never be given until they really need it, and during bright sunshine a sheet of newspaper should be thrown over them until they have become well established. The temperature should be the same as that in which the seeds were raised—fifty-five to sixty degrees by day and fifty by night—until the plants have filled the pots with roots, when they may be kept cooler and gradually hardened off. The final planting out may be done as soon as possible after the departure of frost and when the soil is in good working order. Their permanent places should be determined beforehand, and the soil made rich with fine manure. Where large collections of hardy plants are grown it is always found best to set apart a piece of ground, away from the flower-garden proper, for use as a reserve ground or nursery, where seedlings can be cared for until they reach their normal size and strength. From this they may be moved to any desired situation without any fear as to their ultimate success. This is a plan that should be adopted by all who can spare the space, for gaps are sure to occur in the borders every season, and one has only to turn to the reserve ground to fill them all up, and if a friend wishes to exchange, a young thrifty plant is always available for that purpose. Should any new or rare plants be received, and they are planted among established plants, the food provided for their nourishment is speedily devoured by their hungry neighbors, whereas if nursed by themselves, with others newly planted, all have an equal chance. The reserve ground will be found useful, too, when cut flowers are wanted, and this saves the border from depletion. When planting we make a trench with the spade, put manure in the bottom, and cover with an inch or so of soil. Then we place the plant against the side of the trench, and if the roots have not been confined in a pot we spread them out and cover first with the finer soil, and when sufficient soil is in, press sidewise with the foot until it is firm. When the roots start they will be attracted downward by the manure, where they will remain out of the reach of harm from dry weather or other trying climatic con-

ditions. When the plants have balls of soil attached to the roots they may be planted in the same way, but care should be taken that the balls of soil are not broken. When treated as we have advised hardy perennials may be raised from seed as easily as annuals, and there is no reason why they should not be grown in every garden.

Passaic, N. J.

E. O. Orpet.

Orchid Notes.

Oncidium curtum.—It is not often one meets with this remarkably showy species in cultivation, and perhaps less often it is seen in a fine condition. When well grown it is the equal of such handsome and popular plants as *O. Gardneri*, *O. crispum* and *O. prae-textum*, and is one of the most attractive *Oncidiums* known.

The "crop-eared" *Oncidium*, as Dr. Lindley designates *O. curtum*, first found its way into cultivation in the year 1847 through Messrs. Veitch, of Exeter, through whom it first flowered, but who at the time gave no information respecting its native country. After this it appears to have become very scarce or altogether lost; and it is only of late years that it has been imported from Brazil, but still not in large quantities.

The botanical characteristics of *O. curtum* are its oblong-ovoid, much compressed pseudo-bulbs, which become more or less furrowed with age. One or two oblong-lanceolate leaves are borne on the summit of each, and from the base arises the branching scape, which attains a length of one and a half to two and a half or more feet. Several flowers closely arranged are produced, and measure about two inches across. The upper sepal is oblong-elliptic, wavy, with a few transverse rich brown blotches on a pale, greenish yellow ground. The two lower sepals are connate beyond the middle, and are colored and blotched like the upper one. The broadly obovate petals are rich chestnut-brown, with a conspicuous, irregular border of bright yellow. This latter color predominates in the large reniform lip, which is deeply cleft in the centre, and adorned with a row or two of irregularly shaped chestnut-brown blotches all round the undulated margin. At the base is a dark red-brown zone surrounding the dark purple-warty protuberances which form the crest, on each side of which is a golden yellow auricle.

During December last several good specimens of this species were flowering here, some of them carrying as many as sixty and seventy blooms on a spike; but the average number was about thirty. This is not the usual season, however, for *O. curtum* to produce its flowers, but about April and May. The plants in question were imported ones, and flowered from their native pseudo-bulbs. Plants which have been thoroughly established in cultivation begin to make new pseudo-bulbs in January, and as the weather becomes more genial the growth becomes more rapid, and is fully made about June or July, after which they begin to ripen. Up till this time the plants may be freely watered, beginning with small quantities and gradually increasing them according to the vigor of the growth. As the winter approaches the supply of water is gradually diminished, until the plants require very little, and at rare intervals. The temperature during this latter season may vary from sixty to sixty-five degrees Fahr., rising to seventy to seventy-five degrees in the summer months.

St. Albans, England.

John Weathers.

Miltonia cuneata is a very desirable Orchid, belonging to a much neglected genus, if we except those species that until recently were called *Odontoglossums*. The subject of this note has been known to gardens since 1843, in which year it was introduced from Mexico. This plant evidently enjoys great heat and much water during the growing season, and it thrives best in small baskets, with very little potting compost, which may consist of very sandy peat. It is an erect growing plant, with conical bulbs, and pale green, thin, leathery leaves about a foot long. The erect scapes spring from each side of the base of the bulb, and bear seven to nine handsome flowers distantly placed along each side of the rachis. The narrow sepals and petals are dark chocolate, tipped and barred with yellowish green; the wedge-shaped lip is pure white, tinged with pink near the base. The flowers last quite a long time in water, and are very suitable for cutting.

Kenwood, N. Y.

F. Goldring.

Anemone blanda and *Iris Bakeriana*—Both these are excellent winter-blooming plants. If potted at intervals from August to September and housed afterward in a greenhouse they may be had in flower from November to February. *Anemone blanda*, a near relative of *A. Apennina*, is a native of the Levant, and has the advantage over the latter of flowering

in the open air, four or five weeks earlier—that is, about the second week in March—with me. The plants form a low mass of palmate, much-divided leaves, and the deep blue flowers are from three-fourths of an inch to an inch in diameter. *Iris Bakeriana*, a native of Kurdistan, was introduced by me only two years ago. Treated in the same way as the Anemone, it will flower at the same time. It is a near relative of *I. reticulata*, has lavender standards, white falls blotched with blue, and a deep blue-black tongue. It is powerfully violet-scented when the sun shines upon it, and is very beautiful on account of the harmonious coloring of the flower.

Forestry Matters in New Hampshire.

To the Editor of GARDEN AND FOREST :

Sir.—The Forestry Commission has held two public hearings—one at Littleton, in the heart of the mountain summer resort region, the other in Manchester, the largest city of the state. The leading men of Littleton attended, with many from adjacent towns, and there was a large and spirited meeting. After brief addresses by members of the Commission there was a general expression of interest in the preservation of the forest scenery as the chief attraction for summer visitors. The importance of good roads and of keeping the roadsides and adjacent forests in an attractive condition was urged, and a plan was suggested for the employment of an equipped organization of firemen in each town, under the direction of a state officer, the men to be paid when in actual service fighting forest fires. Most of those present seemed to think favorably of judicious and limited action by the state, but the main emphasis was upon the necessity of individual effort and the importance of action by the towns of the region in improving the local conditions, and thus making the mountain country more interesting and agreeable to visitors.

Some of the men who had all their lives been familiar with the mountain woods, emphasized the fact that fishing is one of the principal attractions for many men from the cities, and that cutting off the forest at once puts an end to the fishing throughout the area thus uncovered. As the fish can live and thrive only in the shade, they leave the streams at once when the sun is let in and warms the water.

At Manchester the manufacturers, merchants, lawyers, bankers and newspaper men of the city were well represented, and there were many farmers from remote towns. Some of these had had experience in tree planting, and the meeting was much interested in their description of methods and results. The love of trees and feeling of delight in them, without which it is so difficult to do anything in forestry matters, was very manifest at this hearing, and if those who are thus vitally interested can be brought into co-operation with each other something may be accomplished.

There is more intellectual movement in New Hampshire of late than for many years before, more thought about the general interests of the people of the state. The agitation regarding forestry subjects and the discussion about abandoned farms mutually stimulate each other. It happens that circumstances bring home to us here with unusual directness the close relation between good taste, beautiful scenery and the qualities of an advanced civilization on the one hand, and the means of subsistence on the other. This is the situation in briefest terms—while our mountain forest-scenery is preserved it attracts multitudes of visitors, and sustains a summer resort business which brings into the state perhaps two millions of dollars every year. This revenue goes into general circulation and thus benefits the whole state. But if the forests are destroyed there will be no beauty or attraction here for anybody. The tourists and boarders will go elsewhere, and our mountain hotel property will be worthless.

But the owners of forest-lands do not keep boarders; they depend on the sale of their timber for their means of subsistence. So here are conflicting interests. The only way out that appears practicable is for the lumbermen to cut off the woods by an orderly method and system, not all at once, "smack and smooth," as the axeman's phrase is, but by taking out the large timber and leaving all below a certain size to grow for another crop. Handled in this way the forests will yield perpetual revenues. The lumbermen can be always cutting, and yet forest conditions will never be destroyed. The ineffable charm of the mountain scenery will be permanent. The myriads of visitors will return year after year, and successive generations of their families will seek a summer dwelling among our hills.

The danger is that we shall not adequately appreciate the necessity of popular education in the broadest sense of the term, of the general propagation of right ideas regarding the facts of the case, and all the interests and relations involved. It is indispensable that the lumbermen and owners of timber lands should be engaged and interested in the movement for the preservation of forest conditions in the White Mountain region. The lumberman's right under the law to do what he will with his own is invincible. If he should not help us, but stand stubbornly on his right to cut off his own timber in his own way, and to make a desert of his own domain if he chooses, we should accomplish very little. We must secure his co-operation, or the practical results of our efforts will be but slight.

Franklin Falls, N. H.

A Late African Novelty.

To the Editor of GARDEN AND FOREST :

Sir.—I notice in your excellent paper for January 29th an account of that much bespoken novelty, *Kalanchoe carnea*, which impels me to say that a reasonably extensive experience leads me to consider it one of the least satisfactory introductions of the last thirty years. Beauty is not a quality either of its flowers or its foliage. The color of both is washed out and mawkish, the perfume of the flowers is agreeable but weak, though of the many exaggerated statements that have been circulated concerning the plant, the common account of its fragrance is perhaps the least beyond the truth.

I enclose a photograph of the plants of *Kalanchoe* that have been cultivated in my greenhouses, so that you can see that I do not speak without knowledge; and my advice to other cultivators is to choose some other subject for hope and experiment.

New York.

C. A. Dana.

Spanish Moss in Northern Tennessee.

To the Editor of GARDEN AND FOREST :

Sir.—In August of last year, while engaged in geological work along the Cumberland River, I came across a locality where the beautiful, pendent tufts of *Tillandsia usneoides* abound. It is on the face of a great limestone bluff which overhangs the river, and has a full southern exposure. The bluff, known to boatmen as the "Checkered House Bluff," is something more than two miles below Cumberland City, in Stewart County, Tennessee, and about fifty miles a little north of west from Nashville. The face of the bluff has a scattered growth of Cedar, Oak and other plants upon it, and the trees over a large area are richly ornamented with the drapery of this hanging and luxuriant plant.

Vanderbilt University, Nashville, Tenn.

Vegetables Under Glass in New Jersey.

To the Editor of GARDEN AND FOREST :

Sir.—It is not an easy matter to find Jobstown on the map of New Jersey, although the place has been made famous for years by the Rancocas stock-farm, from which Parole, Iroquois and many another thoroughbred has gone out to carry the Lorillard colors to victory. The visitor who is now so fortunate as to be shown through the great stables by McLaughlin will find the day too short to listen to the history of the purple-blooded celebrities in their stalls and watch the graceful movements of the youngsters at their exercise. There is not so much to stir the blood in the greenhouses, which stretch away in a continuous line for nearly 1,000 feet, but in them one can see what is perhaps the most successful experiment in this country, on a scale of such magnitude, in raising vegetables for market under glass. This business is carried on by Mr. John G. Gardner, who was the gardener in charge of the establishment here, when it was the custom to furnish its owners in their city home with melons, pineapples and strawberries, green corn and peas—in short, from twelve to fifteen kinds of "home-grown" fruit and vegetables for Christmas dinner. Mr. Gardner now rents the houses and turns his experience and skill to good account in producing fruits and vegetables of the highest quality, and commanding, of course, the highest prices.

It was on the 5th of February when I made my pilgrimage to Jobstown, but the Swamp Maples were red with bloom on the banks of the Delaware; the narrow ribbon of green grass along the water-courses was broadening out and invading the brown stubble in the meadows, and forehanded farmers were plowing in the uplands. As I stepped from the cars I heard

the meadow larks singing, and April was everywhere, stirring all the life in the ground and in the air. Some Nectarine-trees in sunken pots were ready to burst into bloom, and I inquired of Mr. Gardner whether he did not fear the consequences if freezing weather should suddenly come; but he pointed out that on all these flowering shoots there were enough buds, still dormant, to ensure a crop if the precocious ones should freeze; and this explains why so many car-loads of Peaches come to market from Delaware after a serious frost when the buds are swollen has seemed to justify the prophecy that the crop is ruined. These Nectarines in pots, by the way, show what the houses will be called upon to do a little later on. In a general way it may be said that the business here is the growing of Tomatoes and Mushrooms in winter, with Grapes, Figs, Nectarines and Peaches as summer crops. Of course other vegetables are grown, but the Tomatoes and Mushrooms are the main crops.

Many details of the cultural practice here have already been given in GARDEN AND FOREST (vol. ii., p. 5), but the ability to grow good crops under glass is only one of the qualifications for success in the business. The producer must know his markets, and know just what will pay best at a given time, and while having his crops ready in their due season he must arrange for succession in his houses so that the entire space is constantly utilized to the best advantage. In no two of the houses are the rotations exactly alike. In one of the long pits outside, for example, I observed a row of thrifty Tomatoes, just showing bloom, a row of Beans just starting in a long trough-like box extending through the middle of the pit, while pots of *Adiantum cuneatum* were set closely on the front wall. A crop of Cucumbers and one of Asparagus had already been grown in the same pit—the Cucumbers first, trained along under the glass, and the Asparagus roots on the bottom. One large house was filled with tall Tomato plants, trained to a single stem and running up a cord to the roof. They were still bearing well, but would soon give place to other Tomato plants which are now three weeks old. In this house are Vines permanently planted, from which the grapes were cut in November. They were then pruned, laid down and boxed in, to keep them cool and dark before the Tomatoes now bearing were brought into their present position. In April these Vines will be lifted to their places to start, and the second crop of Tomatoes will all have been gathered before the foliage of the Vines shades them injuriously. In another house, where the second crop of Peas is nearly marketed, and where the temperature has been kept low, heat is now gradually admitted, to start the buds of Nectarines, grafted on Plum stock and trained fan-shape along the roof. In another house still, where the first crop of Tomatoes began to yield in November, a second crop is now setting fruit, and after this is marketed the house will be occupied with Figs. These are examples of rotation in different houses; and there will always be a fresh lot of plants ready to take the place of an exhausted crop until the last pot is brought in with a Peach-tree or Grape-vine for the summer.

Mushrooms are growing everywhere in unexpected places, not only in the regulation, deep, dark cellar, but in the side pits, under the staging of the cool houses, and even in the warm houses, where the shutters over the beds are covered thickly with straw for the unusual purpose of keeping the heat out. No Asparagus is now being forced, and the roots are all thrown out. This year the southern Asparagus appeared in New York as early as the 25th of January, and, of course, this arrival breaks the market at once. The increasing competition from the south makes it necessary to know what is going on there every year, so that the grower here can adapt himself to the changing situation. It would not have paid to grow Strawberries for the last holiday season, when Florida was in the market with good berries by Christmas. Hot-house berries grown at that season are necessarily expensive when the days are short, and perhaps dark and foggy; and so few people are willing to pay five dollars a box for berries, that a consignment of fifty boxes will overstock the market. Strawberries at a dollar a basket in March or April are much more profitable, for they are more easily grown in the longer and brighter days, and while the buyers are few who will think of paying five dollars, many a one will take the berries at a dollar or a dollar and a half a basket when southern berries are selling for ten cents a quart. Of course the hot-house berries are better in color, form and flavor than any out-door berry can be after long carriage. It was in preparation for this spring demand that the fine Strawberry-plants, now just coming into bloom here, were layered about the 20th of last July. In August they were potted, and the strong, well developed, single crowns promise an abundant yield. Sharpless is the variety which Mr.

Gardner prizes most highly. While on the subject of varieties it may be said that Sion House is the kind of Snap Bean planted generally here. It gives a crop in six weeks from seed, the pod is of fine size and of a deliciously sweet flavor. Rollinson's Telegraph is the frame Cucumber preferred.

No variety of Tomato has been found superior to the Lorillard, which originated here from seed of Perfection fertilized with pollen from Acme. The plants have been kept pure by raising them from cuttings up till the present year. The good points of this Tomato are, its uniformity of size, good color and shape, rich flavor, and a solidity which continues till the fruit is well ripened. The plant, too, has a strong constitution. Ignotum has a good, bright scarlet color, but it lacks uniformity. An Ignotum tomato that will weigh a pound is not uncommon, but many of them are corrugated. The Lorillard will average three or four to the pound, and tomatoes of this size, especially when all are round and smooth, sell more readily than those which weigh from half a pound to a pound. Of the Ignotum, only one out of five will prove of good form, while of the Lorillard nearly four out of five will be of perfect shape. Perfection may be named as the second best Tomato for forcing. Paragon would be valuable, but it fails to color about the stem. Four Tomato plants are grown in a box two feet long and eighteen inches wide, as was described in the article before alluded to. I noted that where the roof was low and the plants had a height of about four feet, the yield had averaged fifteen tomatoes to the plant, or say fifteen pounds to each box. Where the plants had room to grow about six feet high, each vine averaged twenty-six to twenty-seven tomatoes, or, since they were somewhat larger than the others, thirty pounds to the box. A fair wholesale price would be fifty cents a pound. The plants begin to yield about ninety days from the seed.

Mr. Gardner finds the market for winter vegetables enlarging every year. The number of growers are multiplying still more rapidly, however, and success can only be won by the best cultural practice, the widest knowledge of the demands of the market, and the alertness and enterprise to occupy new fields promptly.

"What are you doing with so many Grape-vines in pots?" I asked, when about to leave.

"They are Black Hamburgs, and I sell a good many. You see they will all bear a fair crop this year. When a man builds a grapery he does not like to wait three or four years before he gathers fruit. These potted vines can be set in between his permanent vines, and give almost immediate returns. Since they are to be discarded it is not bad practice to let them bear heavily now. Those which I do not sell can be made to yield me paying crops."

Recent Publications.

Manual of the Botany of the Northern United States, including the district east of the Mississippi and north of North Carolina and Tennessee. By Asa Gray. Sixth edition, revised and extended westward to the one hundredth meridian by Sereno Watson and John M. Coulter, with twenty-five plates, illustrating the Sedges, Grasses, Ferns, etc. Ivison, Blakeman & Co., New York and Chicago, 1890.

The fifth and last edition of "Gray's Manual" appeared in 1867. A great advance has been made during the twenty-seven years which have elapsed since its publication in the knowledge of the plants of the region it covered; and the want of a new edition to contain the results of the author's own investigations and those of a number of botanists in different parts of the country, whose early botanical inspirations were largely derived from the early editions of this very work, the constant companion for more than forty years of every one who has studied the flora of eastern America during that time, has long been felt. Professor Gray himself proposed at different periods during the last part of his life to snatch the time from the more important "Synoptical Flora of North America" for a new edition of his Manual, but just the right time never came, and it has been left to Mr. Watson, and his associate, Professor Coulter, to produce, with such assistance as was available, this new and greatly improved Manual. The original plan of the work, so long adhered to and of such general acceptance, has been retained, but the territory covered in the old edition has been extended westward to the one hundredth meridian of longitude—that is, to the western limits of our true Atlantic flora. This change and the insertion of such plants of the old region as are now first included in the Manual increases the bulk of the volume by only fifty-seven pages, and therefore does not take away from its value as a book for field reference. The work seems to be admirably done, and so far

as we have been able to examine it, absolutely free from those annoying typographical errors which it is well nigh impossible to eliminate from a book of this character.

Botanists who believe in the strict application of the law of priority in matters of nomenclature will not derive much comfort from Mr. Watson's decisions in such matters, as they appear in this volume; and they will regret that the fulfillment of their hope for a stable nomenclature for plants, as regards both generic and specific names, must be delayed in this country, at least, by the system adopted in a work which will, of necessity, influence for many years the opinions of the students of botany in the United States. But the authors of the new Manual, in their decision that the specific name first given to a plant, when referred correctly to its genus, is the correct specific name for it, although it may have had a much earlier one in another genus, have the support of many of the most distinguished naturalists of this and of the last generation. The name, however, is not by any means the most important part of the plant; and the object of the Manual is to enable any one finding a plant growing in wood or meadow to identify it readily, and to learn something of its affinities and history. No book ever published fulfilled this object better than "Gray's Manual," which will gain in usefulness and reputation in this new edition, for which the authors will receive the thanks of every one interested in American plants.

Mr. Watson acknowledges the assistance of Mr. S. B. Bebb, of Illinois, who has rewritten the genus *Salix* for this edition; of Professor L. H. Bailey, who has elaborated the difficult genus *Carex*, and of Professor D. C. Eaton, who is the author, as he was in some of the previous editions, of the part of the volume devoted to the Ferns and allied orders. The increasing interest taken in this country in the study of cellular Cryptogams has led to the inclusion of the *Hepaticæ*, omitted in the last edition, and now described by Professor L. M. Underwood. A glossary of botanical terms is appended to the volume, besides a Synopsis of the Natural Families, arranged in their sequence, in order that their characters may be clearly contrasted and the general principles which determine their arrangement showed—a new feature in the Manual, and a most useful one.

Periodical Literature.

In *Harper's Magazine* for January we may read of "The Smyrna Fig Harvest," which, though gathered from a very small district, supplies the world with almost all its dried figs. Classic memories fill the air as one travels by railroad from Smyrna, first to the village, which stands where Ephesus once stood, and then along the valley of the Meander where the bottom lands are covered with the Fig orchards. "The soil of this tract is very deep and has the property of retaining moisture so necessary for the crop. This peculiarity is of special importance, as in cases of drought the Fig-tree does not generally show at the time signs of drooping. The leaves retain their strength and color. It is only afterward, when the fruit should have reached maturity, that its stunted size and diminished yield show the effects of the check." The fig grown for drying is a short pulpy fruit, quite unlike the ordinary black eating fig, being bright yellow-green outside, and inside white with a red centre, and, in spite of its abundance of juice, having a poor and rather faint taste. Spring brings no especial beauty to the Fig orchard, as the tiny flowers are borne on the inside of a hollow fleshy receptacle, which later ripens into the fruit. "About the middle of August the figs begin to fall and then all the population of the neighboring villages is poured into the gardens . . . gathering up the fruit and piling it into the baskets. . . . At first the gleanings are over the whole garden. The figs lie as they fall, and the sun has ripened only the most forward of them. But by the end of August the heavy fruit drops so thickly that the pickers will fill a basket with what they gather up from under a single tree," each basket forming a heavy load for a woman. The picturesque appearance of the orchard at this season, with its groups of gaily dressed laborers, is well suggested in the illustrations given. The figs have but a short distance to fall, and "are generally picked up whole. If they lie on the ground for more than twenty-four hours they rapidly spoil. The next step is to dry them. A bank of earth is raised some six inches high and strewn with rushes, and here the figs are laid out in single layers, touching one another. The contact does not last long. The September sun is so hot that in a week the fruit is all shriveled up, and when the figs are but half their original size, the time has come for storing and packing them away in bags." The best are called "Eleme" figs, and these, whether of first, second or third quality, are

exported, while the fourth quality is used at home as food for cattle, and in the manufacture of a cheap spirit, the refuse serving as manure. It is curious to learn, however, that the seeds of this quality are employed in London in the making of what is called strawberry jam. All the fruit is sent to Smyrna and thence distributed, the fig market in a narrow street offering one of the most animated sights in the city, and large fleets of steamers often lying in the harbor awaiting their cargo of dried fruit. The fruit is sorted in large warehouses, exclusively by women, but the "pulling" and packing is done by men. In pulling, "the fig is drawn between finger and thumb, flattened and split at the stalk, so as to take the form which it preserves when it ultimately is found on the dinner-table. Through the middle and end of August, and through September, the work is carried on, though in the last weeks of this month the supply of figs falls off and only the best pullers and packers are kept. By the second week in October the fig harvest for the year is at an end." About a quarter of a million of pounds of dried figs are annually exported, in addition to the large quantity of inferior fruit that is used at home.

The writer mentions the practice of hanging wild figs on the cultivated trees when these are in bloom, but misses the significance of the operation. This use of the wild fig is a very old custom known technically as "caprification" and its object is to secure the fertilization of the cultivated fruit through the visits of certain hymenopterous insects (*Blastophaga* and *Sycophaga*) which frequent the wild Fig-tree. These insects being thus brought near the cultivated trees, enter the minute orifice of the receptacle of their flowers for the purpose of depositing their eggs, and in doing this convey the pollen of the rare male flowers to the stigmas of the females, which are usually much more numerous in the fig. All this is well known, but the curious part of the matter is how the custom, which has been practiced apparently from an early period, first originated. That its utility and even necessity is fully recognized now appears in the fact stated by our author, that in seasons when the crop of wild figs is light as much as four cents apiece are paid for the wild fruit, and that the profits of the cultivated crop are swallowed up by this outlay. What cunning oriental precursor of Sprengel and of Darwin penetrated the secrets of cross-fertilization?—for without some correct idea of the relation of the visiting insects to the ripening of the fruit, it hardly seems possible that a custom so troublesome and so expensive could have been developed.

The fact that the soil of the valley of the Meander has the property of retaining moisture for a long period makes it the great centre of the fig cultivation in the east, and it is only where similar conditions exist that the culture of the plant can be hopefully attempted. "Some years ago," writes our author, "Mr. West discovered in California a tract of soil which he believed to be almost identical. The climate also was similar. Mr. West took back with him some 300 roots. These Fig-trees have done well. They have made good growth and yielded fair crops, but a sufficient time has not elapsed for the tree to reach such maturity as should test the value of its fruit for preserving. It is only when the trees are from five to seven years old that they begin to bear fruit useful for commercial purposes; but once that age is attained, the tree will yield its annual crop for sixty or seventy, or, with careful pruning, for eighty years."

Orchids at Short Hills, New Jersey.

THE remarkable collection of Orchids in flower at the United States Nurseries is attracting large numbers of visitors this week. The *Cypripediums* alone present a spectacle that would repay the beholder for a long journey. Indeed, in a journey around the world, one could find no collection superior to this in richness, for it contains more than 400 species, varieties and hybrids. Of these, 212 are now in flower, including many of the rarest and most beautiful in cultivation. The only plant of *C. pavoninum* in the country is blooming here for the first time, and with it such choice hybrids as *C. Godseffianum*, *C. Savageanum*, *C. Sallierii* Hyeanum, *C. Fitcheanum*, *C. microchilum*, *C. calurum* Rougieri, *C. concinnum*, *C. Bergrinianum*, *C. Williamsi*, *C. regale* and *C. nitens superbum*, besides *C. villosum giganteum*, *C. apiculatum*, *C. Lawrenceanum pleioleucum*, *C. Mrs. Canham* and many more. Altogether there are 525 plants of *Cypripedium* in bloom, representing 212 varieties.

Of course this genus forms but a portion of the bewildering display of more than 1,000 Orchids which Messrs. Pitcher & Manda have in flower. There is a long list of varieties of *Catleya Trianae*, including the variety *Smithæ*, with dark sepals

and petals and orange-colored throat. *Cattleya Skinneri* also appears in many varieties, including several examples of the choice Alba and one of Arnoldiana. *Dendrobium Wardianum album* and *Lalia Arnoldiana* are shown in good specimens, and, in short, there are comparatively few of the really good Orchids now in flower which cannot be studied in this exhibition. C.

Notes.

The New York Forestry Association, at an adjourned meeting on Monday, was reorganized with Mr. Morris K. Jesup as President and Mr. J. B. Harrison as Corresponding Secretary. Additional particulars will be given next week.

The records of the Park Superintendent prove that the beauty of Central Park is fully appreciated by photographers at least. During the past year 1,700 permits to take photographs in the park were issued, and since January 1st nearly 300 have been bestowed or renewed, most of them to amateurs.

A letter from Para, Brazil, to the *Nation*, says that lumber forms the cargo of ships from New York to that country, a land possessing, scattered in lavish profusion over thousands of square miles of unbroken forests, sixty-seven varieties of the most valuable woods for structural purposes in the world.

The *Illustrirte Gartenzeitung*, of Vienna, recently republished the greater part of the accounts of *Pinus latifolia* in this journal (ii., 496) and *Staphylea Bolanderi* (ii., 544), saying that the tree "is probably quite unknown as yet in Europe," and that the shrub "has not yet been cultivated with us."

In the gardens of the Royal Botanical Society, of England, may be seen specimens of the common English Oak, which have been grown to fill ornamental beds. Planted forty or fifty years ago, they have been kept closely clipped, and are now only from ten to twelve inches in height, forming a dense mass of leaves.

A correspondent of the Philadelphia *Ledger* writes that active steps are now being taken to establish, at the University of Pennsylvania, a thoroughly equipped laboratory of plant-physiology and anatomy. Professor W. P. Wilson will go to Europe in the spring to visit the leading laboratories there, and will secure the best instruments and appliances and have them at the University ready for use next autumn.

Hermann Jaeger, whose death in the seventy-fifth year of his age was recently announced, was a noted German horticulturist, and had long held the position of Grand Ducal Garden Inspector at Eisenach. But he was still more widely known as perhaps the most popular writer in his country upon the practice and the history of gardening. He was a constant contributor to *Gartenflora* and other journals, and one of his books was the large illustrated work called "Gardening Art and Gardens in Past and Present Times," which was reviewed in our columns last year.

Gardeners as well as amateurs often ask why many plants in cultivation flourish best in soils and situations unlike those to which they had been accustomed in their native state. A writer in the *Gardeners' Chronicle* recently answered this question in a few words. In many cases, he said, plants grow wild not in those places which are best suited to them, but simply in those where competition permits them to exist, while in gardens their enemies are kept at bay by man, and the most favorable conditions for their development can be supplied.

The third volume of Dr. F. C. Schübeler's great work on the trees of Norway—"Viridarium Norvegicum"—has just been issued at Christiania. It is a large quarto of nearly 700 pages, and completes the work, in which not only the different species of trees native to the country are described and illustrated, but also a multitude of individuals remarkable for size, antiquity or abnormal development. A voluminous index now adds to the value of the book, and the polar limits of all the trees native to, or grown in, Norway are systematically given.

Florists' reports indicate a fairly good holiday trade in flowers this year, although at New Year's the sales were much smaller than those at Christmas, which was quite contrary to the rule for several years past. The prevailing epidemic undoubtedly affected the season's gaieties, and, in consequence, the demand for flowers. White flowers constantly grow in favor for decorative uses, now being often employed to the exclusion of all others. It is pleasant to find that, as was the case last year, all florists note an increase in orders for boxes of loose flowers, and a decrease of the desire for "set pieces."

A German journal, discussing the complaint of a French amateur that the Provence Rose, beloved of his ancestors, is sadly neglected to-day, states that 200 varieties of this Rose were once in cultivation, while hardly more than a dozen are familiar now. One of them was La Belle Villagoise, which was brought from Egypt in the time of the First Empire by the court surgeon, Antoine Dubois, a famous Rose grower. He gave it to the Tilly family in Halliée, where it may still be seen, while—so the statement goes—it cannot be seen elsewhere. It is described as having pure white petals streaked with a brilliant rosy red.

The Philadelphia Academy of Natural Sciences, assisted by the American Philosophical Society and a number of individuals, has arranged for an exploring expedition to the less known parts of southern Mexico and Yucatan. Specialists in botany and zoölogy will accompany the geologists, whose chief purpose will be to ascertain the general structure of the basin of the Gulf of Mexico, hitherto studied more thoroughly on the Florida side. As yet the archæologist has done more in the countries referred to than the scientific investigator. The expedition was to sail from New York for Progreso, Yucatan, on the 15th of this month.

In the Scilly Isles, where the cultivation of Narcissus flowers for market has become so large an industry, the rains and winds which rage there with extraordinary violence used to play havoc with the flowers, destroying thousands of spikes in a night. Close hedges were planted, but these did not avail against the searching winds. Of late years, however, the flower-spikes are carefully cut off and taken in-doors as soon as the buds begin to burst and just show the color of the perianth. Here they are slightly forced by being placed in shallow pans of warm water. The keeping qualities of the flowers are not injured by this process, while their perfection is secured and their opening is hastened a day or two.

The raising of Peppermint for the manufacture of oil is an important industry in Wayne County, New York. The plants are set out in May, in rows two feet apart, and grow to be about two feet high by August, when they are cut off close to the roots with a scythe and cured in the sun like hay for about twelve hours. The extracting of the oil is done by professed distillers, who are paid by a toll, or by farmers themselves in stills of their own. The still is a wooden vat about four feet high by six in diameter. In this the Mint is packed close by treading, covered with an air-tight lid, and subjected to the action of steam forced in from the bottom. The oil is volatilized by the steam and condensed in a worm, and the mixed oil and water, collected in a receiver, separate by specific gravity. It is said that there are a hundred public stills in the county, and it is locally believed that nine-tenths of all the oil of Peppermint used in the world comes from this region.

A number of prominent physicians of this city met last week for the purpose of protesting against the destruction of the Adirondack woods, because the extraordinary altitude of the plateau, from which still loftier mountains rise, its equable temperature and the hygienic properties of its coniferous trees combine to render it one of the most valuable health resorts in the world, and especially useful for the cure of consumption in its earlier stages. Dr. Trudeau, Chief of the sanitarium for the cure of consumption at Saranac Lake, reports that twenty-five per cent. of the incipient cases of consumption treated there are cured, and the health-giving properties of the region can be attested by thousands. An appeal to all public spirited citizens was drawn up requesting aid in the effort to enable the state to acquire such portions of the wilderness as had been sold, so that it can be held forever as public ground free to all the people of the state.

Dr. Moehl, of Cassel, writes to *Gartenflora* that the pyramidal variety of the European Oak (*Quercus pedunculata fastigiata*) was first seen during the Seven Years' War, in the Dieburg forest near Harreshausen, in Germany, and that its oldest offspring is the fine specimen which stands by the "bowling-green" in the park of Wilhelmshöhe, near Cassel. In the same park are flourishing young specimens of the fastigate Hornbeam (*Carpinus betulus*, var. *pyramidalis*) which have been propagated from a tree growing wild in the Reinshard forest, near Münden. This tree was discovered in the winter of 1871-1872 by a hunting party, and stands in a long plantation of Hornbeams which are only from twenty to twenty-five feet in height, while it overtops them, "like a slender Poplar," to a height of about forty feet. It is known that in the year 1820 an order was given to plant this place with natural seedlings of the Hornbeam, so the tree must be about seventy years old. It is said in the neighborhood that its peculiar habit did not show for many years after planting.

The Waverly Oaks.

THERE is in Belmont, one of the suburbs of Boston, and formerly a part of the ancient town of Watertown, a group of Oaks which has come to be known in recent years as the Waverly Oaks, from the village near which they stand. These Waverly Oaks are, all things considered, the most interesting trees in eastern Massachusetts, and although there are larger Oaks in New England and in the Middle States, a group containing so many large trees is not often seen now anywhere in eastern America. There are in this group twenty-three large Oaks and one large Elm growing on an area of two or three acres. The Oaks are all White Oaks, with the exception of a single Swamp White Oak. They occupy mainly the slopes of a terminal moraine, along the base of which flows Beaver Brook, the "Sweet Beaver, child of forest still," sung by Lowell. The Waverly Oaks are well known to all Bostonians interested in nature, and strangers not infrequently make the pilgrimage to Belmont to look upon these venerable products of Massachusetts soil. It is strange, therefore, that so little has ever been printed about these trees. Emerson, the historian of the trees of Massachusetts, makes no reference to them. Piper, who wrote of the trees of America, and who lived not very far away, in Malden, seems to have overlooked them, and traveled all the way to Stowe to find his typical New England White Oak. Brown, another Massachusetts man who published books about trees, passed them by without a word. The poets and philosophers of Cambridge and Concord, who doubtless often passed by Beaver Brook, make no mention of its great trees, which first appear in print, apparently, in 1881, in *Harper's Magazine*, where Mr. F. H. Underwood, writing of James Russell Lowell, speaks of them on page 262 as "the only group of aboriginal trees standing on the Massachusetts coast"—a statement to which some exceptions might be taken. The Committee on Grounds of the Massachusetts Horticultural Society visited the Waverly Oaks on the 28th of June, 1884, and the chairman, Mr. J. G. Barker, joined to its report printed in the transactions of the

society for that year the other short account of the trees which has appeared coupled with a timely suggestion for their preservation.

This suggestion we desire to repeat and enforce; and that the public may know the beauty of these trees and of the spot where they grow, we reproduce on page 91 a view taken by Dr. W. H. Rollins, of Boston, showing a portion of the group.

The age which these trees have attained and the vicissitudes they have survived entitle them to respect, and the people of Massachusetts might wisely secure their preservation through the purchase and dedication to public use of the land on which they stand.

The age of these old Oaks can only be surmised. One famous naturalist is said to have declared that the smallest of them had existed through more than a thousand years. It is probable that this statement is greatly exaggerated. The largest tree in the group girths seventeen feet three inches at three and a half feet from the ground.* The principal tree in our illustration is smaller, with a girth of only thirteen feet four inches, measured at the same distance from the ground. An actual examination of the wood of this tree shows that it has increased three inches in diameter during the last twenty-four years. Had it made the same rate of growth during the whole period of its existence, it would have been 408 years old, and the largest tree in the group would be, with the same rate of increase, 508 years old. It is probable that they are both younger than these estimates make them. They may have grown less rapidly for several years at the beginning of their life, but there must have been a number of years, probably several hundred, when they increased more rapidly in diameter than they have during the last quarter of a century. The appearance of the trees justifies this supposition. They are still healthy, and are growing with considerable vigor; but there can be no doubt that their period of most rapid development has passed, or that, while they may continue, with proper care, to live and increase slowly for centuries perhaps, they will grow less rapidly now than they did one or two hundred years ago. But after making all due allowance for differences in the rate of growth at different periods in the existence of these trees, it is safe to surmise that the youngest of them had attained to some size before the Pilgrims landed on the shores of Massachusetts Bay, and that the oldest was at that time a tree of some size.

The ponderous lateral branches of these trees, reaching out in every direction, shows that they grew up in the open ground, which must have been cleared four or five hundred years ago, if, indeed, the dry and gravelly soil ever produced any other forest growth contemporaneously with these Oaks.

The Waverly Oaks grow within a few hundred yards of the station at Waverly, on the Boston & Fitchburg Railroad, on a piece of ground directly opposite the property of the trustees of the Massachusetts General Hospital, occupied by the country home of that institution. The whole region

* Messrs. L. L. Dame and Henry Brooks, of West Medford, who are engaged in preparing for publication an account of some of the most remarkable Elms and other trees of Massachusetts, obligingly send the following measurement of the largest of the Waverly Oaks, which stands on a steep slope: At five feet from the lower side, twenty-one feet six inches; at five feet from the upper side, sixteen feet six inches. There is a difference of several feet in the height of the ground at the upper and at the lower sides of this tree, and our measurement of seventeen feet three inches, taken at three feet and a half from the ground on the lower side, is perhaps as correct as any measurement can be made. Other measurements of Massachusetts White Oaks sent us by Messrs. Dame and Brooks are seventeen feet eight inches for the Oak at Bernardston; twenty-four feet five inches for the Oak at Boyleston; fifteen feet ten and a half inches for the Avery Oak at Dedham; fourteen feet one inch for the Elliott Oak at Natick; and thirteen feet seven inches for the Topsfield Oak. These measurements are all made at five feet from the ground. A White Oak recently cut on the estate of Peter C. Brooks, Esq., of West Medford, Massachusetts, measured at eight feet from the ground eight feet ten inches, and had approximately 200 layers of annual growth, as counted by Dame and Brooks.

Mr. John Robinson, in his account of the "Woody Plants of Essex County, Massachusetts," gives the following measurement of White Oaks: The Topsfield Oak, in 1875, had a circumference one foot from the ground of nineteen feet seven inches; the same trunk measured sixteen feet eleven inches at three feet from the ground, and twelve feet eleven inches at five feet from the ground. Two White Oaks on the Burleigh Farm, in Danvers, measured respectively nineteen feet and seventeen feet ten inches, both measurements being made at the ground, the first measuring thirteen feet six inches at six feet from the ground and the second twelve feet at five feet from the ground.

is undergoing rapid development, and houses are springing up on every side. The establishment of a small public park at this place, which need not exceed three or four acres in extent to accomplish this object, would protect the trees from the dangers which now threaten them, and would make a valuable and interesting public resort within walking or driving distance of the homes of a very large number of people.

Mr. J. G. Lemmon, the accomplished botanist of the California State Board of Forestry, discusses the problem of forest fires in the seventh bulletin issued by that board. "It is," he says, "a common observation that forests are usually bordered by a fringe of saplings and these by points and patches of seedlings all apparently flourishing finely and promising a material enlargement of the forest area; and scarce an instance is known where an edge of a forest is dying off by the natural course of events. The question arises, is this a normal attribute of forest-growth, or of forest-development? Did they always thus try to expand, or has some change occurred to them or their environment that now enables them to increase their periphery? The answer to the problem is contained in the two English words—Indian fires. The Indian desired open prairies and intervals for his game, that the latter might find better forage thereon, and also that he might the better mark them for his arrows. With the retirement of the Indian and the suspension of the annual forest and prairie-fires, the forests freely expand, and it is well known that young forests are covering large areas of the eastern United States, and it is believed that the great diluvian plains of the central west and of the Pacific slope might in time be covered with trees, if the practice of modern agriculturists did not serve to prevent their growth, desirable or otherwise. More than all the destructive processes of the lumbermen, and the close grazing of the flocks and herds of the stock raiser, is the ruin of the fire fiend; and against him the blazing forests, the menaced settlements and the ruined inhabitants of California appeal to citizens generally and legislatures especially for instant and adequate protection." It is by fires, as Mr. Lemmon points out, that "young seedlings are destroyed utterly, and usually the saplings are killed off, not consumed, while on a section of country from which the whole tree-growths have been removed after a fire, weeds and brambles will not come in until many years after. And how shall the crying evil of forest fires be stopped, where is the remedy, and who shall apply it?"

Mr. Lemmon is not the first thoughtful observer to ask these questions. The answer, perhaps, is wise legislation, but legislation will be useless unless it rests on public sentiment; and public sentiment in this country will not save the forests until the popular mind is more highly educated than it is to-day upon all subjects relating to the forests and their value to the nation.

The Coast of Maine.

FROM Cape Cod, Massachusetts, to Cape Sable, Nova Scotia, the broad entrance of the Gulf of Maine is two hundred miles wide, and it is one hundred miles from each of these capes to the corresponding ends of the coast of Maine at Kittery and Quoddy. Thus Maine squarely faces the wide opening between the capes, while to the east and west, beyond her limits, stretch two great offshoots of the gulf, the bays of Fundy and of Massachusetts. The latter and lesser bay presents a south shore built mostly of sands and gravels in beaches and bluffs, and a north shore of bold and enduring rocks, both already overgrown with seaside hotels and cottages. The Bay of Fundy, on the other hand, is little resorted to for pleasure. Its shores in many parts are grandly high and bold; but its waters are moved by such rushing tides, and its coasts are so frequently wrapt in cold fogs, that it will doubtless remain comparatively an unfrequented region.

Along the coast of Maine, stretched for two hundred miles from bay to bay, scenery and climate change from the Massachusetts to the Fundy type. At Boston the average temperature of July is 70°; at Eastport, at the farther end of Maine, it

is 61°. No such coolness is to be found along the thousand miles of monotonous sand beach which front the Atlantic south of the Gulf of Maine; and though the coolness of the waters of the gulf precludes most persons from sea bathing, this freshness of the air will always be an irresistible attraction to many thousands of dwellers in hot cities. Again, in contrast with the southern sea-beaches, the scenery of the Maine coast is exceedingly interesting and refreshing. The mere map of it is most attractive. Beginning at Piscataqua River, a deep estuary whose swift tides flow through an archipelago of rocks and small islands, the shore is at first made up of low ledges forming ragged points, connected by sand or pebble beaches, where farmers gather rock-weed after storms. Seaward lies a group of dangerous rocks, the Isles of Shoals. Beyond the tortuous outlet of York River and the Short and Long Sands of York, Cape Neddick and Bald Head lift high rocks toward the sea, and behind them rises Agamenticus Hill, a conspicuous blue landmark sometimes visible from Cape Ann, in Massachusetts. Low and sandy coasts succeed, fronting the old towns of Wells and Kennebunk. Cape Porpoise follows, a confused mass of rocky islets, salt marshes and tidal flats; then more long and short beaches, a lagoon called Biddeford Pool, the mouth of Saco River barred by its washings from the White Hills, more beaches, and so to Cape Elizabeth, a broad wedge of rock pushed out to sea as if to mark the entrance to the land-locked harbor of Portland.

Thus far the coast is sufficiently rich in varied scenery—in shores now high, now low, now wooded and now bare, now gentle and now rough; first thrust seaward in rocky capes, then swept inland in curving beaches, and now and again broken by the outlets of small rivers. Cape Elizabeth ends this scenery, and introduces the voyager to a type still more intricate, picturesque and distinctive. Casco Bay, with its many branches running inland and its peninsulas and islands stretching seaward, is the first of a succession of bays, "thoroughfares" and "reaches" which line the coast almost all the rest of the way to Quoddy. The ragged edge of the mainland becomes lost behind a maze of rock-bound islands, and appears but seldom where the surf can strike it. The salt water penetrates in deep and narrow channels into the very woods, ebbs and flows in hundreds of frequented and unfrequented harbors, and enters into countless hidden nooks and coves and narrows. Sand beaches become rare, and great and small "sea walls" of worn stones or pebbles take their place. Islands, islets, and ledges both dry and sunken, are strewn on every hand. The tides flow among them with increasing force, and the fog wraps them from sight more and more frequently as the Bay of Fundy is approached. Great cliffs are rare until Grand Manan is reached, and high hills come down to the sea only by Penobscot Bay and at Mount Desert; but, on the other hand, the variety of lesser topographic forms is very great. In Casco Bay, for instance, the rocks trend north-east and south-west, and all the crowded islands run out into reefs in these directions. Penobscot Bay presents wide stretches of open water divided by well massed islands, but still preserves a fine breadth of effect; and these islands differ greatly in form and character, according as they are built of hard and glaciated granite or of altered stratified rocks. The border bay of Passamaquoddy is distinguished by fine headlands, which terminate islands, generally lower than the heads. In like manner the sounds and fiord-like rivers differ much from each other. For instance, the Kennebec River is extremely narrow, and many bold knobs of rock turn it this way and that; but the neighboring Sheepscot is fully three miles broad at its mouth, and this noble width contracts but slowly; while the Penobscot above the Narrows takes on such a gentle appearance as to be hardly recognizable as a river of eastern Maine, the general aspect of this part of the coast being distinctly wild and untamable. Doubtless the raggedness of the rocky shore is the first cause of the almost forbidding aspect of the region, but the changed character of the sea-coast woods is a second cause. Beyond Cape Elizabeth, if capes and islands are wooded at all, it is with the dark, stiff cresting of Spruce, Fir or Pine, fringed perhaps with Birch and Mountain Ash. Near Kittery fine Elms and even Hickories may be seen on the open shore, but there is a gradual dying out of many familiar species as the coast is traversed eastward. Thus Holly and Inkberry, together with Prickly Ash, Flowering Dogwood and Sassafras, are not seen near the sea north of Massachusetts Bay. White Cedar, after following the coast all the way from the Gulf of Mexico, dies out near Kittery. York River is said to see the last Buttonwoods, Saco River the last Chestnuts, and the Kennebec the last Tupelos and Hickories. Conversely, this coast has its many forerunners of the flora of the far north. While

the White Pine is met with all along shore north of New Jersey, the Red Pine first appears by Massachusetts Bay and the Gray Pine by Mt. Desert. The Arbor-vitæ is first met with near the Kennebec. The Balsam Fir and the Black and White Spruces show themselves on no coasts south of Cape Ann, and do not abound until Cape Elizabeth is passed. It is the blackness of these dwarf coniferous woods which, with the desolation of the surf-beaten ledges and the frequent coming of the fog, impresses the traveler with the fact that this is a really wild and sub-arctic shore, where strange red-men's names for islands, capes and rivers—names such as Medomak, Muscongus, Pemaquid, Megunticook, Eggemoggin, Moosabec and Schoodic—seem altogether fitting.

The human story of the coast of Maine is almost as picturesque and varied as its scenery. This coast was first frequented by stray French fishing vessels, and first scientifically explored by Samuel de Champlain, whose narrative of his adventures is still delightful reading. Fruitless attempts at settlement followed, led by French knights at Saint Croix, by English cavaliers at Sagadahock and by French Jesuits at Mt. Desert; all of them years in advance of the English Colony of New Plymouth. Then followed a long period of fishing and fur trading, during which Maine belonged to neither New France nor New England, and a genuine border warfare was the result. Two rival Frenchmen also fought and besieged each other in truly feudal fashion at Penobscot and Saint John. Again, while the long French and Indian wars lasted, this coast saw more fighting. The older settlements west of Cape Elizabeth were sacked several times, and even the English stronghold at Pemaquid was captured; but the forest allies of the French Baron Saint Castin were beaten in the end. The numerous French names for points on the eastern coast bear witness to the long French occupation; as for instance, Grand and Petit Manan, Bois Bubert, Monts Déserts and Isle au Hault, and Burnt Coat, apparently English, but really a mis-translation of the French Côte Brûlée.

No Englishmen settled beyond Penobscot until after the capture of Quebec; and when they did, they, as Yankees, had to take part in still more fighting in the wars of the Revolution and of 1812. The settlers first fished and hunted, then cut hay on the salt marshes and timber in the great woods, and in later years took to ship building, and later still to stone quarrying and ice harvesting, and, near Rockland, to lime burning. These works are still the business of the coast. Even hunting is carried on at certain seasons in the eastern counties, where deer are still numerous. All the large Pine and Spruce of the shore woods have been cut; but Bangor still sends down Penobscot Bay a fleet of lumber schooners every time the wind blows from the north; and as for fishing, fleets of more than two hundred graceful vessels may often be seen in port together waiting the end of a storm.

It was about 1860 that what may be called the discovery of the picturesqueness and the summer-time healthfulness of the coast of Maine took place. Only the beaches of the western quarter of the shore were at first occupied by hotels; but when the poor hamlet of Bar Harbor leaped into fame through the resort to it of a few well known landscape painters, it became evident that the whole coast was destined to be a much frequented summer resort. At present, York, Kennebunkport, Biddeford Pool and Old Orchard Beach, together with the Casco Islands, Booth Bay, Camden, Mt. Desert and Campobello, are a few of the more populous neighborhoods; but summer hotels are now scattered all along the shore, and colonies of summer villas of all grades of costliness occupy many of the more accessible capes and islands. Thus there are many cottages at York, and the islands near Portland are fairly covered with cheap structures. Squirrel Island in Booth Bay is another nest of small houses, and Bar Harbor is a summer city surrounded by a multitude of very costly and elaborate wooden palaces. The finest parts of the coast are already controlled by land companies and speculators, while the natives' minds are inflamed by the high prices which the once worthless shore lands are now supposed to command.

The spectacle of thousands upon thousands of people able to spend annually several weeks or months of summer in healthful life by the sea-shore is very American and very pleasant, and the impartial observer can find but two points about it which are in any considerable degree discouraging or dangerous. The lamentable feature of the situation is the small amount of thought and attention given to considerations of appropriateness and beauty by the builders and inhabitants of the summer colonies of the coast. Indifference in these matters works ill results everywhere, but nowhere is lack of taste quite so conspicuous as on the sea-shore. Both corporations and individuals are guilty on this head. More than one

booming land company has hastily divided and sold its rough ledges in rectangular lots, whose lines bear no relation to the forms of the ground, so that houses cannot be well placed. The squalid aspect of the public parts of these settlements, the shabby plank walks and the unkempt roadways, are other causes of reproach. The houses themselves, if cheap, are too often vulgarly ornamented, and if costly, are generally absurdly pretentious. Even the government, which has lately been rebuilding many of the light-house keepers' dwellings, has substituted for the simple, low and entirely fitting structures of a former generation, a thin-walled and small-chimneyed type of house, such as is common in the suburbs of our cities. One of these perched on a sea cliff is an abomination, and might well have illustrated the mournful remark of a recent writer in the *Atlantic Monthly*, who pointed out that American indifference to beauty cannot be caused by the newness of our civilization, for when this was still newer we built both more appropriately and picturesquely than we commonly do now. Again, in the treatment of the ground about their houses, the millionaires of Bar Harbor are quite as apt to err as are the humbler cottagers of Squirrel Island. Smooth lawns, made of imported soil, and kept green only by continual watering, furnish a means of displaying wealth, but they cannot be fittingly united with scenery which is characterized by rough ledges and scrubby woods. On this rough coast level grass will please when it is joined to a house and enclosed by walls. In the open ground it can hardly ever be in keeping. Similarly incongruous are flower-beds scattered over rocky and uneven ground, set between the trunks of Pitch Pines, or perched on the tops of whaleback ledges; and yet such things are common sights at Bar Harbor.

The real danger of the present situation is that this annual flood of humanity, with its permanent structures for shelter, may so completely overflow and occupy the limited stretch of coast which it invades, as to rob it of that flavor of wildness and remoteness which hitherto has hung about it, and which in great measure constitutes its refreshing charm. A surf-beaten headland may be crowned by a lighthouse tower without losing its dignity and impressiveness, but it cannot be dotted with frail cottages without suffering a woeful fall. A lonely fiord shut in by dark woods, where the fog lingers in wreaths, as it comes and goes, loses its charm whenever even one bank is stripped naked, and streets of buildings are substituted for the Spruces and Pines. A few rich men, realizing this danger, have surrounded themselves with considerable tracts of land solely with the intention of preserving the natural aspect; and at least one hotel company, by buying almost the whole of the wild island of Campobello, has saved for the patrons of its houses a large region of unspoiled scenery. The readers of GARDEN AND FOREST stand in need of no argument to prove the importance to human happiness of that refreshing antidote to city life which fine natural scenery supplies, nor is it necessary to remind them that love of beauty and of art must surely die if it be cut at its roots by destroying or vulgarizing the beauty of nature. "Men cannot love art well until they love what she mirrors better," says Mr. Ruskin.

The United States have but this one short stretch of Atlantic sea-coast where a pleasant summer climate and real picturesqueness of scenery are to be found together. Can nothing be done to preserve for the use and enjoyment of the great unorganized body of the common people some fine parts, at least, of this sea-side wilderness of Maine? It would seem as if the mere self-interest of hotel proprietors and land-owners would have accomplished much more in this direction than it yet has. If, for instance, East Point near York, or Dice's Head at Castine, or Great Head near Bar Harbor, should be fenced off as private property, all the other property-owners of the neighborhood would have to subtract something from the value of their estates. And, conversely, if these or other like points of vantage, or any of the ancient border forts, were preserved to public uses by local associations or by the commonwealth, every estate and every form of property in the neighborhood would gain in value. Public-spirited men would doubtless give to such associations rights of way, and even lands occasionally, and the raising of money for the purchase of favorite points might not prove to be so difficult as at first it seems. The present year should see, all up and down the shore, the beginning of a movement in the direction here indicated. In many parts of the coast it is full time decisive action was taken, and if the State of Maine should by suitable legislation encourage the formation of associations for the purpose of preserving chosen parts of her coast scenery, she would not only do herself honor, but would secure for the future an important element in her material prosperity.

Charles Eliot.

Entomological.

An Enemy to the Egyptian Lotus.

IN GARDEN AND FOREST for April 10th, 1889, was an interesting account of the naturalization of the Oriental Nelumbium in New Jersey, by Mr. E. D. Sturtevant, who has done more than any other man to popularize the cultivation of this plant. Beauty and poetry, combined, are represented by the flower and its traditions, but neither will serve to protect it against the sordid prose of insect attack. An enemy has appeared that annually ruins many of the plants, eating their leaves, buds, seeds, and even into the stem. The caterpillar—for it is a caterpillar—is a typical borer, living primarily in the leaf and flower stems; but as soon as buds form, they are attacked; the larva bores into the side and feeds so judiciously that the bud continues to grow, and will even open in due time, only to fall apart and to show a mass of black frass in place of a beautiful flower. The seed-pods also are attractive to the larvæ, and the seeds are eaten before they attain maturity. Unfortunately the insects seem to be increasing in number, and bid fair to render Lotus-growing unsatisfactory. To Mr. J. Turner Brakeley, of Bordentown, I owe my introduction to the larvæ infesting these plants, the specimens sent me being from Mr. Sturtevant's ponds. According to the statements made, the larva, when it first appears, lives on the outside of the leaves in a little silken tent, but very soon gets under cover somewhere, either in bud, stem or seed-capsule, whichever is most handy. It continues its work during the summer, and in fact until frost puts a period to the life of the leaves. It was in the latter part of July when specimens of infested stems, buds and seed-capsules reached me, and there were sometimes three to four larvæ in a single stem. In general color the caterpillars are a dirty white, with a more or less evident reddish tint, and rather stout of build, the head and dorsal plate smooth, yellowish, mottled with red-brown. Each body segment has two larger dorsal yellowish tubercles, one large tubercle each side, and usually two smaller, also yellowish, tubercles near the posterior end of the segment. The annexed figure will give a fair idea of the general form, and the mouth parts or instruments of destruction are also shown in detail. When full grown the larva is nearly an inch in length, and then spins a rather flattened cocoon of a quite dense texture inside the stem and changes to a blackish brown pupa about half an inch in length. Towards the middle and latter part of August the moths issued, and proved to be a species of *Botis* not previously described. From its food plant I name it *Botis nelumbialis*.

In general color it varies from a pale clay yellow to a powdery, rusty red, all intervening shades being represented. Two dentate dark lines cross the wing, one near the base, the other toward the outer margin of the wing. Usually there is a dusky discal spot and a dark shade close to the outer margin, but sometimes only the median lines are visible. The

Fig. 19.—*Botis nelumbialis*, Smith; varieties.

figure shows three forms of the new species, about natural size. These insects promise to become quite a serious pest, and it is not easy to suggest a certain remedy. Black-birds are said to eat the larvæ, while they are exposed. Where there are but a few of the plants, they can be easily kept clean by picking them off before they take to shelter. It is probable that in their method of passing the winter we shall have an opportunity to control them. If, as I suspect, the winter

Fig. 18.—*Botis nelumbialis*, Smith; a, larva from above; b, a single segment from side, showing sculpture; c, mandible of larva; d, maxillæ and palpi; e, clypeus; f, antenna; g, leg. All greatly enlarged.

the water line, the cut material to be buried deeply enough to prevent all chance of the larvæ working their way out.

Rutgers College, February 8th, 1890.

John B. Smith.

New or Little Known Plants.

Gladiolus Turicensis.

WE are indebted to Messrs. Froebel & Co., of Zurich, for the drawing from which has been made the illustration, on page 89, of *Gladiolus Turicensis*, concerning which they send the following note:

"Mr. Max Leichtlin, of Baden-Baden, was the first to improve garden Gladioli by an infusion of the blood of *G. Saundersii*. The first variety obtained in this way he named *G. Saundersii superbis*. In 1880 we produced two varieties by crossing *G. purpureo-auratus* with *G. Gandavensis*, which we named *G. Froebeli* and *G. Engesseri*. These were both good varieties, and proved perfectly hardy. *G. Brineri*, of the same parentage, followed in 1885. *G. Turicensis* is our last production, obtained by a cross between a large-flowered variety of *G. Gandavensis* with *G. Saundersii superbis*. The flowers of *G. Turicensis* are a fine purplish crimson color, the lower segments of the perianth beautifully marked with white. When fully expanded the flowers are upward of three inches across. The flowers of *G. Saundersii* have the bad habit of bending in toward the stem, while those of this hybrid, when fully expanded, look one in the face, so to speak. *G. Turicensis* is a plant of exceedingly vigorous growth, the spikes of flowers attaining the length of two feet. It is a free bloomer, and seems well adapted to plant in beds where masses of flowers of one color are needed."

Should this plant prove, as it is predicted, perfectly hardy, it will make, certainly, one of the most valuable additions to the list of hardy summer-blooming bulbs which has appeared for some time. Whether it is hardy or not, however, it is a plant of great value, which will be watched with interest by all growers of Gladioli, not only for the beauty of its flowers, but as an element of possible future improvement in garden varieties of Gladiolus.

Foreign Correspondence.

Berlin Letter.

HYACINTHS bloomed much earlier than usual this year, such varieties as Homer, Maria Cornelia, Wilhelm I. and Norma being in flower from ten days to two weeks before their usual season. The same remark is true of the Tulips, and it is interesting to know that the bulbs grown here are forced more easily and flower earlier than Holland bulbs, a fact which has been known to Berlin gardeners for some years past. The culture of spring bulbs, which was once a prominent industry here, has fallen off within the last ten years, but the tide has again turned, and large fields of Hyacinths, Tulips and Scillas can now be seen, a result largely due to the energy and enterprise of Mr. Spath. Old gardeners say that the bulbs have not flowered so early as they have this year since 1840. They attribute this fact to the very hot and dry May of last year, which in their opinion ripened up the bulbs quickly and perfectly. I am not sure, however, that this is the true cause. It is well known that plants which suffer so much from dryness, or any other cause, that they are in danger of death, at once begin to develop flower-buds. It is as if the instinct of the plant for the preservation of its species asserts itself whenever the individual plant is threatened with extinction. Every gardener knows that plants which are to produce abundant foliage should be well fertilized, while plants which are needed for bloom should be kept in more or less sterile soil. In consideration of this it is my opinion that the early flowering of these bulbs is really due to the hot and dry May, although not to the fact that the bulbs were ripened well, but rather because in their enfeebled condition they followed the general law and gave all their energies to the production of bulbs.

This opinion is based on practical experience. To decide this and many other questions with accuracy would require the work of horticultural experiment stations, but these are entirely lacking in Germany. We have fine horticultural schools where gardeners may learn all that is necessary for them to know, in practice, of plant life, but a station in which experiments can be made on the same broad scale as they are made in the agricultural stations has not yet been established in Germany. How strong the interest here is in the education of young gardeners appears from the fact that the Royal

Fig. 20.—*Gladiolus Turicensis*.—See page 88.

Land Culture Commission, in November last year, recommended a grant for a horticultural school, as well as the establishment of a branch for horticultural art in one of the high schools of Dresden. The establishment of a horticultural academy similar to the agricultural academies is merely a question of time, but more necessary now than all this seems the establishment of a horticultural experiment station. The questions to be solved are so numerous that opportunities for usefulness would at once present themselves.

An event of the first importance will be the great International Horticultural Exhibition which is to be held in Berlin from the 25th of April to the 5th of May. Hitherto such exhibitions have been great plant-shows where the public could see the progress of horticulture in well grown specimens. Now and then there was a space for garden-plans, or a carpet-bed attracted attention. Sometimes, also, arrangements of cut flowers were to be seen; but this exhibition will have some entirely different features. Exhibitors will have opportunity to show the public how plants can be used for decoration on different occasions. Two large banquet halls—each one sixty-two and a half feet wide by eighty feet long—will be provided, and these, with the tables, are to be decorated in competition. Then there will be a chapel to show decorations for nuptial ceremonies, baptisms, etc., and besides these, ten rooms, each twenty-three feet long and twenty feet eight inches wide, to be considered as parlors, dining-rooms, etc. This will give opportunity to show how different rooms can best be decorated for different occasions. There will be two yards connected with houses, one furnished with porticoes and the other with balconies, both of which are subjects for competitive decoration, not to mention windows, pergolas, pavilions and the like. The entire exhibition palace will be 625 feet in length and 295 feet in breadth, with a hall for meetings, one for exhibitions, and one for landscape-gardening and horticultural literature.

Other space will be divided as follows: For the decorative display, 4,200 square feet; for stove and greenhouse plants, 14,000 square feet; for Roses, forced flowering shrubs, perennial plants and bulbs, each 3,150 square feet; for nursery products, 7,200 square feet; for cut flowers, grasses, etc., 2,650 square feet; for vegetables and fruits, 650 square feet.

Besides these there will be hot-houses, greenhouses, etc., usually in full operation, so that Orchids and other stove plants will find comfortable quarters in a hot-house constructed within the exhibition limits. The houses are all to be entered in competition, as will be the boilers and other methods of heating. A large hall in connection with the exhibition palace will be devoted to garden implements and machinery.

This exhibition, international as it is, will show phases of gardening quite different from those seen in the older ones. The number of medals and prizes is enormous. The Emperor himself has offered a large gold medal as the highest prize. It would add greatly to the attractiveness and value of the show if American gardeners would offer examples of their art, so that their styles of decoration could be compared with those which prevail here. That foreigners can compete here with success was proved at the last Chrysanthemum show in November, when two English gardeners received the first prize, the gold medal. Large collections are already in preparation in the Riviera for this exhibition. One nurseryman alone is preparing to send four railway cars full of Palms, Crotons and the like.

Palm culture in the open air is making some headway in Germany. In the Berlin botanical gardens this winter, which so far has been very mild, an experiment has been made with *Chamærops excelsa*. In Altenburg, Thuringia, a Mr. Köhler has succeeded, it is said, in growing *Phoenix*, *Pritchardia*, *Chamærops*, *Cocos Weddelliana* and *Cycas revoluta* out-of-doors.

In the flower shops now *Azalea Indica* is the prevailing plant. Besides these, forced Roses of remarkable merit abound, and though the prices are very high there is a great demand for them.

Udo Dammer.

Cultural Department.

Fern Notes.

THE remarks of Mr. Watson in his London Letter of a few weeks since to the effect that popular interest in Fern collections in England seems to have fallen to a low ebb of late years, reminds us that a very similar state of affairs prevails on this side of the ocean, for while attention is frequently called to the rapid increase in numbers and varieties contained in the various collections of Orchids in the United States, in both private and commercial establishments, yet the Fern collections in the same wide territory, that are worthy of special

mention, may perhaps be counted on the fingers of one hand. Now this is not intended to imply that the Orchids are not worthy of all the publicity that has been given them, but merely as a statement of fact, and though fine Ferns are seen at some of the exhibitions, yet it must be conceded that they are somewhat scattered.

While there is no doubt that the use of small Ferns in floral arrangements has very largely increased during a few years past, and that in consequence they have been grown by thousands in a number of commercial places, yet the species and varieties so grown are very few, being limited to some of those easily-propagated and rapid-growing sorts that require but little special attention. In fact, a list of a dozen to fifteen names would comprise those most used in this way, and might read as follows: *Adiantum cuneatum*, *A. pubescens*, *A. gracillimum*, and in smaller quantities *A. Farleyense*, *Pteris serrulata* and *P. serrulata cristata*, *P. Cretica* and its varieties, *P. argyræa*, *P. tremula*, *Onychium Japonicum*, *Davallia tenuifolia stricta*, *Asplenium Belangeri*, *Doryopteris palmata* and *Nephrodium Sieboldii*. Occasionally a batch of *Lygodium Japonicum* is seen grown on the same plan as *Myrsiphyllum asparagoides* (that is, on strings for wreathing), but this is usually in limited quantities.

It would, however, be quite an easy task for any Fern-lover to compile quite a long catalogue of distinct species that may readily be grown in cool-house temperature (about forty-five degrees at night) and in a house so located as not to be entirely satisfactory for the cultivation of flowering plants. In such a house may be grown a number of different types, from moderately developed tree-ferns down to such charming miniature ferns as *Davallia parvula* and *D. alpina*.

Among the larger growing species specially adapted to cool-house culture may be mentioned some of the *Alsophilas*, as *A. australis*, *A. excelsa* and *A. Capensis*, all of these being noble species and of vigorous growth. *Dicksonia antarctica* is an indispensable sort for this purpose, being highly ornamental either in a small plant, or when it has attained its full development and presents a massive trunk twenty feet or more in height and possibly one foot in diameter. *Dicksonia squarrosa* and *D. Youngia* are also admirable species and somewhat smaller-growing than the foregoing. *Dicksonia Barometz* is another valuable fern of strong growth, though not arborescent in habit. This plant throws up its dark green bipinnate fronds to a height of five to six feet, the fronds being freely produced from a very hairy decumbent rhizome.

In this genus is also to be found one of the handsomest large Ferns in cultivation; *Dicksonia Schiedeii*, with long pendulous fronds which sometimes attain a length of twelve to fifteen feet. The fronds are bipinnate, light green in color and glaucous on the under side, and the stipes and crown of the plant being densely covered with silky hairs adds much to its attractiveness. *Brainea insignis*, the only member of its genus and a native of China, is also a valuable addition to any cool-house collection. It is of moderate growth, the fronds averaging from two to three feet in length, and is said to develop a trunk four or five feet high, though there are probably but few of that size in cultivation, its growth of trunk being very slow. *Woodwardia radicans* and *W. orientalis* are very easily-grown cool-house species, the former being especially graceful in habit, its long pendulous fronds hanging down like a delicate green drapery, and in a good specimen frequently attain a length of six to eight feet. Another interesting point in connection with this Fern is the proliferous habit of its fronds, the young plants being produced in quantity on the upper surface of the frond. A number of the *Pteris* and *Aspleniums* are also suited to this purpose, prominent among the former being *Pteris scaberula*, an excellent Fern either as a specimen or for cutting, though it has one drawback in being partly deciduous in the winter.

The well known *Pteris argyræa* and *P. serrulata* in its many forms are too widely distributed to need further recommendation at this time. It may be added that the large-growing Ferns to which attention has been invited will also be found of great utility as out-door ornaments in summer, providing they are placed in a somewhat sheltered and shaded position and well supplied with water.

Protection Against the Striped Cucumber Beetle.

THE striped Cucumber Beetle (*Diabrotica vittata*, Fabr.), is a most malignant enemy to battle where it has once gained possession of the field. The oft-printed formulas that abound in our horticultural journals generally prove signal failures when put to the test in anything like a severe attack. At best, applications to the foliage are expensive and more or

The Waverly Oaks.—See page 85.

less detrimental to the plants. Gardeners and entomologists are at last pretty well agreed that some protection placed over the hill before the plants appear above ground will prove most satisfactory in the long run. The fact that such protection often aids materially in preventing injury from frost is an important point in its favor, as the *Cucurbitaceæ* are among our tenderest open-air plants.

Fig. 21.—A Simple Plant Protector.

The protector illustrated in the accompanying sketch has the merit of being strong, light, durable and economical of storage, as well as being entirely efficient and cheap. The difficulty with most of the plant-protectors in use is that they are too fragile, too costly or too bulky for convenient storage. The one here shown is made of five-eighths-inch undressed pine lumber, covered over the top with ordinary wire mosquito netting. The frame may be made sixteen inches square at the top, and the sections are cut so that the bottom is slightly larger, giving flare enough to admit of nesting the boxes together for convenient storage. By cutting the boards in the manner shown in the drawing, they may be "double-nailed," which greatly adds to the strength of the frame without increasing the weight or cost.

University of Wisconsin, Madison.

E. S. Goff.

Orchid Notes.

Arides Roebelenii is now flowering here. It is one of the later additions to this extensive genus, but is no great acquisition. It much resembles *A. quinquevulnerum* in its erect, sturdy habit and dark green, glossy leaves. The ascending racemes are about one foot long, bearing about thirty flowers, small and greenish white, with a fringed incurved lip tinged with rose at the apex. There is little to recommend this species except its free blooming quality and the pleasant fragrance of the flowers. It was introduced some five years since from the Philippines, and grows freely in the warmest house.

Odontoglossum Rossii was imported in such vast quantities a few years ago and sold so cheaply that it became the best known of the genus; but, to keep it in good condition for any great length of time, it should be given the treatment recommended for *Lælia anceps* and other Mexican Orchids. It quickly deteriorates in the damp, sunless houses usually occupied by this genus. It is an extremely free blooming kind, and a well grown plant is literally covered with flowers, which remain a long time in perfection in a cool, dry atmosphere. It is admirably adapted for cutting, and if a number of plants are grown and care is used in forcing or retarding the flower-buds, they may be had in bloom more than half the year. *O. Rossii* has a very wide distribution in Mexico, and in some localities it grows in immense quantities. There are also a great many varieties, consequent on the great variation of climate; and in some few cases on supposed cross-fertilization with allied species. Since the variety Majus was introduced the typical form appears to be lost, for one seldom hears of plain *O. Rossii*.

Odontoglossum elegans, a very rare and beautiful plant, is flowering freely with us. It is supposed to be a natural

hybrid between *O. cirrhosum* and *O. cristatum* or *O. Hallii*. The habit and inflorescence much resemble those of *O. cirrhosum*, but the flowers are larger and have broader segments. The color is pale yellow, with heavy blotches and bars of reddish brown, and a purplish crimson blotch near the base of the petals. The narrow lip is reddish brown at the base, with the front portion white; the crest is yellow, and the column white. The plant was introduced from Ecuador about ten years since, and but few are now in cultivation. It grows freely at the warmest end of the cool-house, but requires a good season of rest and must not be overpotted.

Kenwood, N. Y.

F. Goldring.

Vanda Amesiana is one of the most pleasing of the Orchids now in flower. I lately saw a large number of plants, each bearing several spikes of bloom, in the houses of Messrs. Low & Co., of Clapton. The flowers are so delicate and pretty, and, moreover, are so deliciously fragrant, whilst the plant itself has such a healthy, business-like appearance, that this species cannot fail to become one of the most useful and popular of tropical Orchids.

Kew.

W.

Brussels Sprouts.

THE seeds of this excellent form of Cabbage should be planted in the house, hot-bed or greenhouse as early as the first of April, as it requires a long season to perfect its growth. The young plants resemble those of the Cauliflower, and will be large enough to set in the open ground as soon as the weather and soil favor a free growth; till then they should be kept in flats of earth, not crowded, and they may need more than two transplantings. If so, each change will have a tendency to develop roots, and if the plants have also been exposed to the free air and sunlight, they will be strong and healthy. A soil to grow Brussels Sprouts should be strong, and also well enriched. The early part of the season's growth is required to develop stature and leaves to the plant; later in the season, the leaves, beginning with those first formed, and near the ground, fall off, and from their axils buds or small heads of Cabbage develop spirally around the stem, and quite as thickly as they can cluster. This process continues till fall. At maturity the plants having the most perfect collection of buds are saved for wintering. Some never have heads large enough to use, and some will bloom like a green Rose; these are failures. Take up the selected plants before the hard frosts, with abundance of earth; bring them into a cool cellar, either light or dark; set the roots not too close together in the ground, give them water once, and the season can be prolonged till the spring months. The green worm is as troublesome as it is to other members of the Cabbage-family, but the plants are quite hardy, and repay the endeavor to grow them.

They are prepared for the table by first separating them from the stalk and removing the imperfect leaves. After lying in salt and water for half an hour, they are boiled for twenty minutes in water to which a little soda has been added, and are served with either cream, butter, or vinegar sauce. They have a very pleasant cabbage-flavor, peculiar to themselves.

West Springfield, Mass.

W. H. Bull.

Doronicum Harper Crewe.—This is a most interesting plant, belonging to the *Compositæ*, with flowers of the very brightest yellow, somewhat larger than a silver dollar, with about forty-four very narrow florets. As a winter-blooming plant in a cool greenhouse it is most effective, the flowers remaining wide open all night. The leaves are heart-shaped, of a very dark green, and growing close to the soil. I have plants in six-inch pots which have been in flower for two months, and at no time have there been fewer than three flowers at once. It delights in a sunny position and a temperature of forty-five to fifty degrees at night. This plant can be recommended as a very good subject for amateur culture.

Seed-Sowing.—The many failures experienced in the germination of very small seeds, such as those of Begonia, Gloxinia and Calceolaria, is the result of too deep covering in nine cases out of ten. My plan of treating all small seed is this: I use light sandy loam, which is heated to a temperature of 120 degrees; one-half is then passed through a sieve having meshes half an inch in diameter. This is then spread to the depth of an inch in boxes. The other half of the soil is passed through a sieve having meshes a quarter of an inch in diameter, and a portion of this is spread over the first soil, made very smooth by being slightly pressed with a board having a planed surface. The seed is then evenly sprinkled over it, and in the case of very

fine seed it is not covered at all with soil. The whole is then carefully watered with a fine rubber sprinkler. Seeds such as Aster, Stocks and Primroses are covered with soil to the depth of about the thickness of the seeds. The finest seeds are covered with sheets of glass, on which is kept a single covering of paper, either an old newspaper or light packing paper. The coarser seeds are covered only with paper, and at no time until germination takes place is any direct light admitted. After germination the paper is removed at night, and again replaced for a while during the day-time. A safe temperature for most seeds is from fifty-eight to sixty-five degrees.

Pearl River, N. Y.

John Thorpe.

Lachenalia Nelsoni.—The admirers of hardy plants owe a debt of gratitude to the late Rev. J. Nelson for the valuable garden varieties of the common Moss Pink (*Phlox subulata*), which were originated by his skill, and have proved so valuable in the spring garden. Many other admirable hybrids were produced by this enthusiastic amateur, and among them the one named at the head of this paragraph. Of all the *Lachenalias* we have tried this is best adapted to general use. The flowers are bright coral-red in bud, and golden yellow when expanded; they are borne on stems six to eight inches long just above the foliage, which is prettily mottled with brown. The value of *Lachenalias* as winter-blooming plants lies in the durability of their flowers, which last in good condition for nearly two months. Nothing is more simple than the culture of these bulbs. They should be potted in September, three in a four-inch pot, and in winter kept in a light place, where the temperature does not fall lower than forty-five degrees; they will then flower in January and February. After flowering the foliage soon dies down, when the bulbs require no water until potted again in September. There is no reason why these plants should not become popular for window-culture, as the conditions necessary to the successful flowering of a *Geranium* in winter suits *Lachenalia Nelsoni* admirably, both, in fact, being the offspring of plants native to South Africa.

Passaic, N. J.

E. O. Orpet.

Christmas Roses.—My experience with this species of *Helleborus* and its varieties agrees with that of Mr. Gerard. This winter and the preceding one cannot be accepted as a test of their hardiness. Even protected by the ordinary hot-bed frames and sashes, I am far from believing that they would flower during a winter as severe as that of 1884-85. To induce them to flower in such a winter the frame would need the further protection of a lining of litter besides mats and shutters. Cultivated under such conditions, they lose their claim to be considered hardy, and above all, their charm. The majority of people who cultivate hardy plants can enjoy them only as such, and they should not remain under any delusion about Christmas Roses.

Wellesley, Mass.

The Forest.

The Need of a Forest Policy in Pennsylvania.

THE need of a more rational system of forest management is as great in Pennsylvania as in any of her sister states. That this has been a settled conviction on the part of many thinking men is apparent from the frequency with which forestry matters have been discussed before her agricultural and other societies. In 1881 the State Board of Agriculture appointed a committee on forestry, which, in the succeeding year, rendered a carefully prepared report, which was the result of inquiry in every part of the state, and gave answers to the questions as to (1) the approximate amount of old timber in each county, (2) the amount of young growth, (3) the best protection against fires, (4) the legislation which seemed desirable, together with some others of less moment.

These inquiries developed a widespread feeling that, although Pennsylvania had been one of the best timbered states of the Union, there was now need of a husbanding of the remaining forest resources, and some encouragement to reforestation and protection from fires. How to secure these ends gave rise to various suggestions more or less practicable, which, from time to time, were brought to the attention of the Legislature. But they appeared—at least to the Legislature—to lack distinctness and purpose, or to be impracticable, and nothing came from them. In 1888 the Governor of the Commonwealth, acting under a joint resolution of the Legislature, appointed a committee of five citizens to consider and report upon the forests of the state, and to recommend legislation if they saw fit. No provision was made for the expenses of such committee, and it was left to determine its own methods and

scope of work. None of the committee felt that, under the circumstances, any considerable personal examination of the forest-condition and needs of the state could be made; hence they sought to obtain all the information possible through correspondence. And by personal letters chiefly, and a circular to county officers and corporations, collected a large number of facts as the basis for their report.

The report which they rendered was a brief and compact résumé of the general forestry question as it exists in the eastern United States to-day, fortified by various facts and considerations which had special bearing on the condition in Pennsylvania. That a more elaborate report was not presented was, perhaps, a disappointment to some, but it was felt that, in the absence of authentic and definite information, a longer report, founded, as it must have been, on general principles alone, would carry no additional weight, and might even be of lessened value. Accompanying the report was the draft of a bill, which it was hoped might commend itself to the Legislature. The main features which it embodied were as follows:

The appointment of a permanent forestry commission of three members, with power to elect a secretary, who is the working member of the board; also such wardens and agents as they may deem necessary, and to define their duties. The duties of the commissioners were to ascertain the true state and condition of the forests of the commonwealth; their relation to the needs and industries of the people; the rate of destruction by different means, and the prosecution of offenders of the laws relating to forests. The means necessary to accomplish these purposes were detailed as fully as seemed practicable.

Circulars or bulletins of information on forestry methods were to be issued for the benefit of landholders. The subject of forestry was to be brought before the teachers of public and normal schools and various associations by a lecturer to be provided by the board, and by the distribution of *Forest Leaves*, the publication of the Pennsylvania Forestry Association. Special effort was to be made for securing better observance of the laws regarding trespass upon and firing of forests, by the posting of notices of these laws in all suitable places.

After presentation to the Legislature the bill was referred to the Committee on Agriculture for further consideration. The advocates of the measure were granted a hearing before this committee, and endeavored to explain further the intent and value of it. No direct report or reply was ever received as a result of this interview, but it was understood that the bill was considered to be impracticable, even in a modified form, and it was never reported back to the House.

Whatever may have been the defects of this bill, it was framed with the intent to meet what many believe is a growing, and soon to be an imperative, need in our state, namely: Some systematic care and attention to the conservation of our forests, and their perpetuation over those large areas, chiefly mountainous, which ought to be not only continuously productive, but also centres of salubrity, and checks and barriers to climatic extremes. Meanwhile, the interest in forestry has continued to increase, and, although most active and visible in the eastern part of the state, is nevertheless becoming more and more evident in the others, and includes the intelligent, thinking men of various occupations and surroundings. From letters received from correspondents it seems in place to note very briefly the opinions of three, which may be taken as representative.

A farmer and lumberman of one of the north-eastern counties says: "The time is near at hand when no question will be of more vital importance to the Pennsylvania land-owner than that of how best to restore the wasted woodlands of the state. In solving this problem there is abundant room for both thought and work. It will not be wise to leave the work of restoration wholly in the hands of Nature, for while Nature can do and is doing much to reclothe the waste places in our forests, Nature does not always, in selecting species, give us those most useful to us, nor can she unaided successfully cope with tramps and incendiaries, private and corporate, whose carelessness or malice often, in a few hours, destroys the work of years. How can Nature's generous efforts in our behalf be best assisted? The state can do something. The act of June 1st, 1887, is good as far as it goes, but it does not afford adequate protection against irresponsible depredators. Forestry associations can do something, but much must be left to individual work. We have learned only too well how to get rid of trees, we need now to learn how to replace them. We shall find the last problem a harder one to solve than the other."

An engineer in active service with a mining company, having written a letter to the *Scientific American* on the timber

supply and forest-condition of northern Pennsylvania, says: "I wrote the article to which you refer entirely from a sense of duty—to raise the alarm, to call attention to the fact that people were being misled in the matter of bark and lumber supply left in the northern part of this state. Men who have traveled only on the railroads or who get their information from some one who is trying to 'boom' a county or section of country, write as positively on this subject as those who have traversed the valleys and climbed the hills where the lumberman is carrying on his work of destruction. I have none but a general interest in the matter—no lands, or bark, or timber for sale, nor do I expect to have; but it grieves me to see such ruthless destruction, such vandalism—if I may apply the word to the destruction of our forests—as is going on all around us. I am quite well acquainted with the condition of things in Tioga, Lycoming, Sullivan, Potter, Elk, Forest, Jefferson, Clearfield and Cameron Counties, but my knowledge of the state of affairs in McKean and Warren is quite limited. . . . One thing you may rest assured of, I put the case in its simplest form in my letter to the *Scientific American*."

One of the foremost politicians of the state, himself a large landholder and business man, says: ". . . Sooner or later these lands (those which have been stripped of their timber) fall back upon the county through arrears of taxes. The time is coming, if not already here, when the need of some adequate forestry laws will be seriously felt."

State College, Pa.

William A. Buckhout.

Correspondence.

Australian Trees in California.

To the Editor of GARDEN AND FOREST:

Sir.—The issue of GARDEN AND FOREST for December 4th mentions the probability of the Kauri Pine being adapted to California. That it will flourish in certain portions of the state is not a matter for surmise, as a stately specimen of the tree forty feet high stands upon the grounds of Mr. Sawyer, at Montecito, near Santa Barbara; nevertheless, neither the planting of this nor its equally beautiful and hardy congeners, the *Dacrydiums*, have been prosecuted to any noticeable extent in California.

Hitherto the impression has prevailed that *Acacia* and *Eucalyptus* were about the only genera that would conform themselves readily to our conditions of soil and climate; and the wonderful collection of Mr. Ellwood Cooper, at Santa Barbara, and the successful growth of no less than forty-six species of this latter interesting genus at the State Forest Station at Santa Monica, have helped, perhaps, to give color to this theory.

At this date (December 16th), and at this station, unprotected seedlings of *Lagunaria Pattersoni* are appearing vigorous and healthy, and when it is recollected that this tree is a native of the tropical Queensland "scrub," we may be warranted in holding somewhat optimistic views of the possible future expansion of the Australian silva in this state.

Outside of the *Leguminosæ*, *Protaceæ*, *Myricaceæ* and *Sterculiaceæ* our gardens and parks show a striking poverty in Australian plants—a poverty only less regrettable than the absence from them of our native trees and shrubs.

Mr. F. M. Bailey, in his recent (1888) monograph on Queensland woods, enumerates 537 species, of which only twenty-eight per cent. are tropical or ultra-tropical, leaving nearly 400 species of extra-tropical sorts that would doubtless accommodate themselves to various parts of California.

The locality first mentioned (Montecito) is exceptionally favored, even for California. Sheltered from strong winds, near enough the coast to insure the atmospheric humidity requisite for most jungle plants, and practically exempt from frost, it furnishes the climatic requirements of a semi-tropical arboretum.

In the gardens referred to is a noble Laurel—the *Persea gratissima* (Alligator Pear)—which, in August last, was fairly loaded with green fruit, and from which I recently received ripe fruits. In the same grounds, and amongst a unique collection of Palms, stand regal specimens of *Archontophoenix* (*Seaforthia*), *Cunninghamiana* and *Cocos plumosa* quite twenty feet in height. These two Palms, though no uncommon features of Santa Barbara gardens, have nowhere else in the state made themselves so fully at home. Ultimate success with Australian and other exotic plants in California depends upon close and impartial observations and records of soils and climate. The lowest official temperatures recorded at Los Angeles during many years past is twenty-eight degrees, and by private record only twenty-six degrees has been touched; yet six miles distant, at the Ostrich Farm, the mercury has fallen to

fourteen degrees—an amount of cold which killed the immature wood of *Nerium Oleander*, and quite sufficient to have destroyed any Queensland tree yet introduced here.

On the other hand, six miles in another direction (the Cahuenga) the Coffee shrub and *Artocarpus incisa* (Bread-fruit-tree) have grown unimpaired by frosts during four years; and though no authentic meteorological data are at hand from that quarter, the evidence shown is sufficient to warrant the hope for a liberal measure of success with even tropical Australian plants. The natural advantages of this point or of Montecito for acclimatization gardens are far superior to those of the Stanford Arboretum, and probably have no parallel upon this coast or within the United States.

Los Angeles, Cal.

William S. Lyon.

The Action of Root-hairs Illustrated.

To the Editor of GARDEN AND FOREST:

Sir.—A letter from Mr. James E. Reeves to Professor Joseph Leidy contains the following statements: "You may have noticed in the Associated Press dispatches two weeks ago, report of the re-interment of the remains of the Confederate General Walker, who was killed in the battle before Atlanta, July 22d, 1864. The specimen I have the pleasure of sending you is a part of the mossy network which completely covered the remains."

"The burial place was in a dry ferruginous clay, and the vault preserved unbroken by a thin crust arch which prevented the falling in of the superincumbent earth; and thus the remains—which consisted of nothing more than the bones, and some of these broken into dust—were all easily brought into view, with their remarkable covering."

Through the kindness of Professor Leidy I have had the privilege of examining the fragment of this "mossy network." I find it to consist of the ultimate rootlets of some plant, whether herb, shrub or tree I have no means of knowing. But the most striking thing revealed by the microscope is the vast number of root-hairs with which these rootlets are covered. It is quite clear what their function was. In fact, they afford an illustration of the absorbing powers of such appendages. Through their activity the mortal remains of the brave Confederate soldier had already had their resurrection into a new life by the leaves and flowers which covered his grave.

The fact taught by these root-hairs is well recognized, but I have never before seen so striking an illustration of it.

University of Pennsylvania.

J. T. Rothrock.

Kalanchoe carnea.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. Dana's opinion of this plant will be endorsed by most cultivators; and yet the *Kalanchoe* has merit as a window-plant. It bears the dry atmosphere of hot rooms; it wears well, and its perfume is very agreeable where confined; and it may be much improved by selection. Already I notice some plants with decidedly brighter colors than the rest. It may be possible to cross it with some brilliant-colored species of *Kalosanthes*, such as *K. coccinea*, and if so, we may hope for some really valuable additions to our list of plants. I well remember how insignificant were the earliest comers among the Chinese Primroses (*Primula Sinensis*), with their puny flowers and insipid coloring. By selection extending over thirty-five years we now have some of the most beautiful colors and the most effective early winter-flowering plants in a class of plants that was once almost despised.

The California Fruits and How to Grow Them. By Edward J. Wickson. Dewey & Co., San Francisco. 1889.

Perhaps no country in the world excels California in natural adaptation to the production of fruit and its preservation. It combines the three great advantages of abundant heat, continuous sunshine and dry air, and these, taken in connection with a soil admirably suited for fruit-culture and a long growing season, ensure an abundance of fruit, which matures early and is of good quality. Besides this, the rainless summer, with its dry heat and steady sunshine, gives exceptional advantages for curing fruit in the open air. All these conditions would naturally prompt Californians to engage in fruit-growing; but when we consider how recently this industry was in its infancy, and consider, too, that the pioneers in the enterprise came from regions where the climate was radically different from that of California, we cannot but wonder at its rapid development. Of course many mistakes were made in the

beginning, and as there were no traditions of culture and no experience to rely upon, the early fruit-growers were compelled to experiment for themselves. Fortunately, they were men of exceptional intelligence, and the reports of their papers and discussions at the meetings of the State Agricultural Society and other bodies gave great aid to new-comers. It is rather remarkable, nevertheless, that so complete a book as this of Mr. Wickson's could be prepared out of actual experience in the orchards and gardens of the state. This manual is very comprehensive in its plan, treating generally of the climate of California and its modifications, giving full cultural directions to the fruit-grower from the proper method of clearing the land and of planting the nursery down to the preparation of the fruit for market. No doubt it will be found of great value to all those who are desirous to embark in fruit-growing in that region, but who have no practical acquaintance with the methods or materials to be used. The book, however, will find many readers outside of California. The wonderful variety of orchard fruits, semi-tropical fruits, small fruits and nuts, whose cultivation is here described, will astonish those who are not familiar with the resources of the Golden State. Very interesting is the chapter on the wild fruits of California and on the old fruits that were introduced into the early missions. The section of the work relating to the preservation of fruit is comparatively brief, but to the eastern reader it has a peculiar attraction on account of the magnitude of the operations which are there described.

Exhibitions.

Flowers at the Water-Color Exhibition.

THERE are some fair flower pictures in this year's water-color collection, but none of remarkable excellence. Miss Greatorex has sent none of her large paintings in which the color of great masses of blossoms is insisted upon with such splendid decorative effect; Mr. La Farge none of his exquisite little studies where the whole of a blossom's beauty is shown and a soul is suggested for it that only the poet's eye can see in nature; and Mr. Weir none of those dainty Roses which are dreams of flowers rather than real flowers. Instead we have a number of little works where simple portraiture of a more prosaic sort is attempted, and a few where a general decorative effect has been tried for, with flowers as the main but not the only motive.

Perhaps the most important of all is Miss Hooker's "Carnations," a large picture with the yellow, pink, white and dark red flowers, half in a white glass bowl and half on a white table-cloth. The composition is effective, the lighting well conceived, and the flowers well drawn, and neither too rigid nor too soft. In color the general effect is excellent, but this result has been attained by some sacrifice of strength of tint in the flowers themselves. Were they as truthfully portrayed in this as in other respects, there would be no deficiency to note in an excellent picture. By comparison all the other paintings of Carnations on the wall seem poor enough. As a rule the form of the flower has been neglected; we see only a featureless mass, sometimes too hard, more often too soft, without the vigor of outline or the beauty of detail which give a Carnation its character.

Roses are even more in favor this year than Carnations, usually one of the double pink hot-house varieties being chosen. Here again the chief fault is lack of form—or, perhaps, lack of substance. Even when the form is well made out the Rose looks as though it were composed of some wishy-washy material instead of the pliant yet thick, the soft yet waxy, the delicate yet heavy material that Nature uses. Much the best Roses in the collection, I think, are those by Miss Grace Pomeroy, which are unfortunately skied over a door in the west room. They are only a few flowers simply placed in a common ginger-jar, with the white paper for background. But they are well drawn, frank and true in color, and firm in body without being in the least "hard" in the painter's sense of the word. It is especially pleasant to see the foliage as well executed as the flowers, and not allowed to fade away into the background as though of minor importance. Miss Pomeroy calls these Roses *Bon Silène*. Would not a florist call them *Papa Gontier*? Miss E. E. Lampert does not paint Roses badly, but neither is her work exceptionally good; and most of the others who have tried them may well be left unnamed.

A different kind of work is called for by Hollyhocks, and Mrs. Nicholls' bold touch and nice feeling for brilliant color have represented them well, in tall stalks with white and red

blossoms. A delicate little picture is Miss Abbat's "White Sweet Scabious," where the flowers are grouped with other objects and the general color effect is good. Most of the Pansies are blotchy and watery—devoid of texture although nicer very often, in color. E. M. Scott sends some *Nasturtiums* in a glass bowl which deserve mention; Miss Williams an excellent study of pink Chinese *Primroses* growing in a pot, and H. A. Pressey a group of *Azaleas* in a green glass bowl, remarkable for the delicate completeness with which the fragility of the greenish white petals and the exquisite pliant outline of the blossoms are rendered. Miss Redmond's "Grapes" should not be overlooked, though they, too, are "skied"—California Grapes, blue, red and green, as hard, yet velvety and juicy, as the sun of the Pacific had made them.

But much the most interesting pictures of flowers in the collection are two which lie outside the customary limits of flower-painting—two landscapes in which masses of growing flowers form the dominant feature. One is Mr. Ross Turner's brilliantly handled "Garden of Lilies, Bermuda," where we see a Lily plantation in the foreground, with touches of brighter hues to relieve its borders, white houses in the middle distance, and the background on a slope of vivid green and interspersed with blackish evergreens, and a cloud-flecked sky that is likewise frankly green, although, of course, quite pale in tone. We can believe anything of the color in Bermuda, such marvels have so often been told us; and Mr. Turner's sky proves its verity by its harmony with the other tones in his clear scheme of color. His Lilies are really not painted at all; there is just a stretch of white paper flecked with yellow, to stand for their mass. But this mass is suggested in such delightful fashion that we are content to forget for once that Lilies have beautiful forms, enjoying the radiance of the snowy sheet which is stretched before us.

The second flowery landscape is Mr. Bunker's "Aster Garden." Here we have the summer of the north as against Mr. Turner's winter of the south; and it is hard to choose between their contrasting charms. Nothing could be more attractive to eyes tired of our winter's bareness than this huddled garden corner where great masses of China Asters (painted, like Mr. Turner's Lilies, for color effect simply) grow beneath a hedge of Sweet Peas, with *Coreopsis* starring the tall grass in front of them, and what seems to be an orchard stretching its shadowy breadth in the background. Of course, this is not the way to paint flowers when one wants to show the flowers themselves; but when it is their effect that is wanted—their beauty as they grow in masses of softly blended or sharply contrasted colors—then few water-color painters of the day could expect to succeed better than Mr. Turner and Mr. Bunker have succeeded here.

New York City.

M. G. Van Rensselaer.

Meetings of Societies.

At an adjourned meeting of the New York Forestry Association held at Columbia College on Monday afternoon, February 10th, a revised Constitution was adopted, and the following officers were elected: President, Morris K. Jesup; Vice-Presidents, Dr. C. K. Adams, President of Cornell University; Grover Cleveland, Willard Cobb, Mrs. D. G. Croly, George William Curtis, Rt. Rev. W. C. Doane, Warren Higley, Seth Low, President of Columbia College; Warner Miller, C. L. Merriam, Dr. J. S. Newberry, Ellis H. Roberts, Carl Schurz, Rev. Dr. R. S. Storrs, Dr. H. E. Webster, President of Union College; Gen. Egbert L. Viele; Treasurer, Thomas Denny, 30 Pine Street, New York; Recording Secretary, E. B. Southwick; Corresponding Secretary, J. B. Harrison, 52 William Street, New York; Executive Committee, William Potts, 35 Liberty Street, New York; Professor D. S. Martin, Edward M. Shephard, Benjamin Strong, W. A. Stiles.

The officers of the Association are *ex officio* members of the Executive Committee, and three members will constitute a quorum for the transaction of business. The Committee is authorized to fill all vacancies, and to elect committees for various purposes, and is clothed with all the powers of the Association as its representative when the Association is not in session. It was provided that no debts can be contracted, nor any appropriation made in excess of the money in the treasury available for the purpose.

The object of the Association is the promotion of effort for the maintenance of forest conditions on the mountain lands of the state. It does not now commit itself to any particular measure as final, or entirely adequate, but it will, as far as possible, co-operate with the State Forest Commission, and with all associations and citizens in favor of any judicious and

practical plans for the preservation and rational management of the Adirondack forests. It will devote itself systematically to the diffusion of knowledge and the propagation of sound ideas regarding the functions and value of this mountain forest region as the source of the great water-ways of the state, as a sanitarium, as a source of timber supply and as a preserve for fish and game. The Association invites the largest possible membership. The fee is one dollar per annum, which should be sent to the Treasurer, whose address is given above.

Notes.

Orange-growers in southern California have sold their Washington Navel Oranges on the tree for \$2.75 a box.

Snowdrops were in full bloom in the open ground in gardens near Boston last week, fully five or six weeks earlier than in ordinary seasons.

The December number of the *Journal of the Japanese Horticultural Society* contains a colored figure of a remarkable green-flowered Chrysanthemum of the Japanese type.

Professor J. T. Rothrock and Professor W. T. Wilson, of the University of Pennsylvania, have become associate editors of *Forest Leaves*, the organ of the Pennsylvania Forestry Association.

The best Baldwin apples from Maine and Canada sold at \$6.25 a barrel wholesale in Liverpool the first week in February; Russets ranged from \$4 to \$5.50, and Greenings from \$4.50 to \$5.

High praise is given in German journals to the Messrs. Henderson's Tuberose Excelsior Pearl, introduced some ten years ago, and to Albino, which they have recently put on the market, but which was first exhibited by Messrs. Mitchell at Chicago in 1887.

We recently spoke of the probability that the Okra-plant would soon be cultivated for its fibre. It is not generally known that in Texas it is already used for making lariats. In France it is used for making paper, and in India it is used to adulterate jute.

The House of Representatives of the General Court of Massachusetts passed a resolution on the 5th of February ordering the State Board of Agriculture to inquire into the condition of the forests in the state, the need and method of their protection for sanitary and other reasons, and the encouragement of tree-planting, and report thereon to the next General Court.

A correspondent from Media, Pennsylvania, sends the names of twenty-three plants which were in bloom there in the month of December. Of these, *Brassica nigra*, *Capsella Bursa-pastoris*, *Lepidium Virginicum*, *Viola cucullata*, *Stellaria media*, *Antennaria plantaginifolia*, *Nepeta Cataria* and *Symplocarpus foetidus* flowered through the month of January.

California journalists call attention to a fact which would seem strange enough in any portion of the globe less diversified in its surface than their state. At the time when the Central Pacific Railroad was blockaded for a week or more by gigantic snow-drifts, Roses were blooming and Oranges and Lemons were ripening their fruit only seventy miles away.

In the last quarterly report of the Kansas State Board of Agriculture the number of acres of artificial forest is given by counties. The totals are as follows: Acres of Black Walnut, one year old and over, 17,054; of Maple, 14,171; of Honey Locust, 3,415; of Cottonwood, 56,760; of other forest-trees, 120,172. The total value of the wood marketed for the year 1889 is placed at \$207,604.

A statue to Mr. James S. T. Stranahan is about to be erected in Prospect Park, Brooklyn, as an acknowledgment of his many services to the city, and especially of the prominent part he played in the establishment of the park itself. It is a pleasure to know that the work bids fair to be a genuine ornament to the beautiful pleasure-ground, as the sculptor chosen is Mr. W. F. MacMonnies, a native of Brooklyn, who has recently been studying in Paris, and of whose abilities Mr. St. Gaudens, his former master, speaks in the highest terms.

The fourth annual Orchid Show, which opens to-day at the Eden Musée, promises to surpass in varied interest any of its predecessors. As in former years, the exhibition will be under the direction of Messrs. Siebrecht & Wadley, who announce that they will contribute from their own collection 800 plants of some 300 distinct varieties in full flower. Besides these,

choice plants from several of the most important Orchid collections in various parts of the country have been sent here at great risk and expense. The exhibition will remain open for ten days.

Herr Otto Froebel, of Zurich, recently explained in *Gartenflora* that, after long experimenting, he had found *Rosa laxa* the best stock for grafting. It is a central Asiatic species, the seed of which was sent him some twenty years ago by Dr. Von Regel. It makes no suckers, easily accepts grafts of all kinds, and is thoroughly hardy in Germany; moreover, its stem naturally grows straight, smooth, unbranched and almost destitute of thorns to a considerable height, so it is especially well fitted for producing standards, while the early ripening of its wood peculiarly fits it for winter forcing.

A new hybrid Rose, raised at the Arnold Arboretum by Mr. Dawson, is just now flowering for the first time. It was produced by crossing the small, white flowered Japanese *R. multiflora* with pollen from the well known hybrid perpetual, General Jacqueminot. The offspring of this cross has the foliage, somewhat reduced in size, the branchlets and the spines of the pollen parent; the flower is solitary (not clustered as in *R. multiflora*), about an inch across, cup-shaped, semi-double, with bright pink petals; and, moreover, it has the real Jacqueminot odor. The plants, as far as they have been tried, are perfectly hardy, while most of the so-called miniature Roses with bright-colored flowers are tender in the severe New England climate.

Mr. Charles Howard Shinn writes from Niles, California, to the *Evening Post* that wealthy men looking for long investments can do something in the Pacific Coast region that will last for many generations, paying a larger interest than almost any manufactory in America. The investment recommended would be as nearly indestructible as anything human can be. He thinks that on irrigated lands on the lower Rio Grande, along the Colorado, or in portions of California, Nevada or Arizona, Date Palm orchards would last for ages and pay a steady profit. The Olive is already planted in large groves by associations looking for safe and permanent investments, but no one has planted a Cork-Oak forest. Dates, Persian Walnuts, the Figs of Smyrna, the Cork of Spain—all of these are constantly increasing in value; the world's supply is not keeping pace with the demand, and they offer new and attractive channels for large investments of capital as safe and permanent, he thinks, as brick blocks on the business streets of growing American cities.

Bulletin No. 63 of the New Jersey Experiment Station is a record of some tests with Tomatoes. From these it appears that nitrate of soda increased the yield invariably, but was most effective when used in small quantities at a time, and, as would have been supposed, when balanced by applications of phosphoric acid and potash. Contrary to a prevalent belief that chemical fertilizers make garden produce watery, tasteless and innutritious, the Tomatoes on the plots where nitrate was used were not only large, smooth and beautiful to the eye, but they were more solid and had fewer seeds than those on the other plots, and the chemical analysis proved their superior nutritive value. The crop was increased by the nitrate from thirty-five to sixty per cent. on the different plots. Considering ten tons an acre an average yield, and \$6.50 a ton an average price, the gain from the use of nitrate ranges from \$17 to \$39 an acre. This would make an important difference in a state where 15,000 acres are devoted to raising Tomatoes for canneries, besides some thousands more where Tomatoes are grown for market.

Botany for Young People.

THE letter entitled "Mocking at Knowledge," which will be found on another page, calls attention to certain misapprehensions which are not uncommon. Indeed, there are many intelligent people who seem ready on all occasions to discourage the study of botany even in its simplest and most attractive forms. They would be shocked if charged with indifference to knowledge of other natural sciences, but they seem to consider a desire to study botany on the part of any young person as a foolish endeavor to pry into a subject so profound that only a "smattering" of it can ever be learned, and a smattering of knowledge is declared worse than entire ignorance. Another objection to the study is that the more one learns about plants the less will one appreciate their beauty. The scientific attitude is held up as the reverse of enjoyment; scientific knowledge is proclaimed to be deadly to artistic or poetic feeling. "Why," it is said by those who should have spoken more wisely, "can any one want to pull flowers to pieces to learn their hideous Latin names? What is the good of it in the end, and must it not destroy all sense of beauty which we, in our happy ignorance, enjoy so keenly?"

No one believes that a knowledge of astronomy destroys all pleasure in the splendor of the midnight sky, or a knowledge of geology all interest in the grandeur and variety of the earth's surface. But trees and flowers must not be studied unless the student is willing to exchange the pleasure of the eye for whatever barren satisfaction he may find in hard names and withered, dissected specimens. It is probable, however, that one cause of this odd belief is the idea that to study botany means simply to learn Latin names, and that the knowledge of these names is its own only end and aim. If this were true botany would indeed be a dry and not very useful study, although there would still be some benefit in being able to speak of plants exactly instead of inexactly, and to speak of any possible plant instead of a comparatively restricted number. But to learn Latin names is only the first step in learning to know the plants they represent—a needful step if one's knowledge is ever to amount to much, but in no sense an end or aim.

When a simple handbook can be used so that the name of a plant can be found in it (the common name, as our correspondent points out, always appearing with the scientific), then all other facts about the plant can be read at a glance; and unless this can be done most of these facts will never be gathered. Knowing the name, we find the manner of the plant's growth, the regions where it is common or rare, the character of the spots where it may most hopefully be looked for, its seasons of blooming and fruiting, and its relationship to other species, with the facts upon which this relationship is founded, as well as those which make its own individuality clear. Is not all this worth knowing, even at the cost of dealing for the moment with the ugliest of Latin names? If a child finds a rosy *Arethusa* with twin blossoms, will not his pleasure in it and his desire to search for other flowers both be stimulated by the knowledge that his treasure is a very rare one? Or if he discovers that the pretty little Bunch-berry which carpets some woody spot is first cousin to the big Flowering Dogwood, and discovers too the reason why, will not his interest in it be increased? Let him learn why an Orchid is an Orchid, why the tiny Ladies' Tresses deserve the name as much as the gorgeous *Cattleya* or *Oncidium* of the greenhouse, and he has gained something which surely cannot decrease his enjoyment of the beauty of either.

But to do this, it may be objected, beautiful flowers must be pulled to pieces, and this will "deadend the sense of beauty." By no means. The truth is quite the other way. No one who has not once pulled a flower to pieces can realize, in the great majority of cases, how beautiful it is. All its beauty is not in its larger features or on the outside of its cup. In the interior, in the hidden recesses where the great work of reproduction goes on in a myriad different ways, each more marvelous and admirable than the other—here resides a great part of the beauty of all flowers and the greater part of the beauty of not a few. Even if it led to nothing but a knowledge of Nature's delight in making the tiniest features of her productions lovely to our eyes, the close examination of floral structures would be well worth many hours of a busy man's time. Once this has been learned, we do not need always to see it. Seeing the flower as a whole, we not only know its name, habits and relationships, but remember its structure. The exterior suggests the interior, and a knowledge of the interior explains the lovely individuality of the envelope.

This is sufficient to prove, we think, that even a smattering of botanical knowledge is better than entire ignorance. Archbishop Whately long ago pointed out that this word has two distinct significations. One of these is a superficial acquaintance with a subject and some pretentious display of slight acquirement. The other simply means rudimentary acquaintance, and must be the beginning of all knowledge. Even the slightest smattering, in this latter sense, of botanical knowledge will greatly increase instead of lessening the enjoyment of any one who by nature has any love for flowers.

But there will be a further gain. Once let a person begin to study plants and he will desire to increase the list of his acquaintances; and then he will use his eyes as he never did before. He will discover beautiful flowers whose existence in the neighborhood none of his mocking friends ever suspected. He will see a hundred things where they will not see ten. Having learned to appreciate beauty on a small scale, he will seek for it instead of waiting for it to strike his eye, and will find it in the most unpromising places. He will delight in the exquisite beauty of the infinitesimal blossoms of the Door-weed on which passive, uninstructed observers will never have perceived a blossom at all; and will be enchanted by the flowers of the Pig-weed even, despised of the multitude, but honored by him as a treasury of interest. Nor, surely, will his new appreciation of such humble charms lessen his feeling for the splendor of the *Iris* he finds in the swamp or the *Meadow Lily* that flaunts by the way-side.

To learn enough to thus widen one's interest in Nature's products is not a very difficult task. Indeed, there is no other science in which a beginning is so easily made or gives so large a return in pleasure. Materials for study are everywhere at hand; no traveling is needed, no great exertion and no outlay of money. The needful tools are as easily procured. A single volume like Gray's "New Manual and Handbook" will give all requisite preliminary instruction, full descriptions of all plants within a very wide area, a glossary of terms to help out the weakest memory, and, as our correspondent says, a dictionary of common names. With a knife, a long pin and a common magnifying glass the student has all he wants; and plants, even when withered and dissected, make a litter to which no mother would object as she might to the materials of the boy who has a passion for flying and creeping things. A few weeks of work, with living plants to illustrate the printed text, will seem more like play than work, and will enable any young person to identify all the plants in the neighborhood of his home. Any one who knows what is meant by such a study of botany as suffices for this purpose, and what is its immediate return in the increase of enjoyment and the development of the observing faculties, may well be astounded that any prejudice against it should ever be harbored. Of all the sciences this is the one whose study should meet with every encouragement as a happy and useful employment for our young folks' summer hours.

In the last annual report of the President of Harvard College, recently issued, Mr. Eliot calls attention to the pressing need of a better endowment for the Gray herbarium than that establishment now enjoys. The income of the herbarium last year was only about \$3,300, two-thirds of which was derived from the copyrights which Professor Gray bequeathed to it. From this slender income, which, so far as regards the value of the copyrights, is liable to diminish rather than to increase as years go on, the salary of the Curator must be paid, the collection must be kept in order and extended, and the library kept abreast of the times.

The Gray herbarium is the national herbarium of America in everything but name. No other collection of dried plants in the new world equals it in size and in importance; and its value for reference will continue, although it is possible that larger collections may in time be formed in better endowed establishments. No other herbarium, however, whatever its financial strength may be, can ever possess so many of the type specimens of the American flora, or can supplant the Cambridge collection as the final place of reference for determining the identity of the plants described by Professor Gray and his associates. No critical student of American plants can take a step in his investigations without referring to the Gray collections, and their value is so great and so generally acknowledged that Mr. Eliot's appeal for a better herbarium endowment cannot long remain without a favorable response.

There is a pressing need in the herbarium of well trained and capable assistants, that the Curator may be relieved of the daily drudgery of caring for the collections, and be left to carry forward the unfinished "Flora of North America," on which Asa Gray worked for nearly half a century and left only half completed. It can be finished at Cambridge only and by an author thoroughly trained in systematic botany. This book is now more needed than any other work of descriptive botany, and no mere financial difficulty should be allowed to stand in the way of its completion.

Mr. Eliot asks for the sum of \$40,000 with which to endow the Gray herbarium. It appears to us that the sum is much too small, in view of the importance and reputation of the collection, and the extent and character of the botanical work the public has learnt to expect from Cambridge. What the Gray herbarium really needs is a permanent endowment which will produce an income of not less than twelve or fifteen thousand dollars; and its greatest

usefulness and efficiency cannot be secured with a smaller sum. Harvard College has for years been supreme in America in systematic botany, and she cannot now allow her position as a leader in this department of knowledge to be jeopardized through inability or unwillingness to properly support her great herbarium, or to pay the price of leadership.

A few weeks ago we spoke with approval of certain bills relating to our public forests which are now under consideration by Congress. It should not be forgotten, however, that the people who wish to convert the timber on the national domain to their own private use are quite as energetic as those who wish to protect it. There are some nominal safeguards in the forms of law already which are supposed to have been enacted to prevent the spoliation of the public forests, but owing to essential defects in the laws or their administration they have proved ineffective hitherto, as is well known. Even these laws, however, are looked upon as too much of an obstacle in the way of free access to the public forests, and a bill of Senator Teller's now before the Public Lands Committee seems to have been devised to enable everybody who feels so inclined to help himself and his friends to all the timber they can use or sell.

The bill is entitled "A bill authorizing the citizens of certain states and territories to fell and remove timber on the public domain for mining and domestic purposes," and it seems well contrived to accelerate forest destruction. The little formalities needed under this scheme to clothe any one with power to take timber from the public forests are to be entrusted to the registers and receivers of the Land Office, who already have more duties than they can properly perform, and altogether the timber-cutters would have a merry time under the provisions of the proposed law.

An Alley in the Tuilleries Garden, Paris.

THE garden of the Tuilleries was laid out, by Le Nôtre, in 1665. Since the Revolution its design has been somewhat modified, but most portions still show the arrangements of the great master of formal gardening design. Upon one side fronted the palace, which was destroyed in 1871, the ground it covered being now laid out with paths, lawns and flower-beds, as described in the article on "French Parterres," published in our issue for January 29th. This change has, however, only increased the beauty of the Tuilleries gardens, for, as we stand in their central alleys, the eye, instead of being stopped by the façade of the palace, looks over the newly planted ground into the vast court-yard formed by the Louvre, where rises the Arc du Carrousel, and beyond it a number of small, park-like enclosures with fine trees. All this large and beautifully arranged place and the great buildings about it were formerly concealed by the façade of the Tuilleries, and, therefore, admirable as this was in itself, its loss is more than made good. Again, standing back within the quadrangle, we now have, enframed in its wings, a majestic perspective unrivaled in any modern city—first, the Arc du Carrousel, then the brilliant new garden, then the massive plantations of Le Nôtre, and beyond them the obelisk of the Place de la Concorde, and past this the long, rising slope of the Champs Elysées, with the Arc de Triomphe standing majestically against the far distant sky. The long, gentle rise in the ground beyond the Place de la Concorde adds vastly, of course, to the effect of the picture, but only a nation with a true instinct for art in its most monumental phases could have utilized it to such good effect and brought it into one great composition with the Tuilleries gardens, a century and a half after these were formed.

The palace faced on one of the narrower sides of the garden as it lay by the bank of the Seine. Along this river-side and the remaining two sides as well, Le Nôtre arranged elevated terraces, planted with avenues of trees. At the western side, opposite the palace, two great curving stairways of marble lead to the terrace and the Place de la Concorde beyond; and smaller stairways rise on the river-side, and, opposite this, to the Rue de Rivoli. In our picture we see the houses that form the Rue de Rivoli, and, in the distance, the tall pavilion which finishes the north side of the Louvre and

once joined it to the Tuilleries palace. The terrace on this side is called "La terrasse des Feuillants," from a convent of Benedictines, or "Feuillants," which formerly adjoined it, and, during the early days of the Revolution, was the rallying place of the moderate republicans. It is thickly shaded with old Lindens, and in summer forms a delightful promenade overlooking, on one side, the busy street, and, on the other, the wide, quiet, graveled space called the "Allée des Orangers." The Orange-trees are wintered in a house that stands near the river, but in summer are set out in long lines, which add vastly to the dignity of the garden by their symmetrical, architectonic shape, and to its charm by the perfume they exhale. Many of the trees are very ancient, but they are well cared for, and, in form as well as profusion of bloom, satisfy the most critical eye. The wooden boxes in which they stand are painted a delicate, dull pale green, which contrasts well with their dark foliage and harmonizes well with the pale tone of the gravel.

The trees shown at the right of our picture indicate plantations of rectangular form which border both sides of another alley, likewise furnished with rows of Oranges. Here, not far away from the point where we stand in the picture, is a little café, ignored of the tourist—a low, isolated building with an awning and tables facing toward the interior of the garden. Stumbling on its quiet shelter, one can realize the blessing that his beautiful urban parks must be to the Parisian. We are thankful for a small, noisy space like Madison or Union Square. But here in the very heart of Paris there is little except the subdued roar of the Rue de Rivoli behind us to tell that a city exists. In front of the tables are Oleanders and Pomegranates blooming in pots; to the right and left stretches the long perspective of thick, straight-edged plantations supported by the lines of Orange-trees, and beyond is the charming reach of flowery parterres which once formed the private garden of royalty (shut off from the main garden by a moat, now bridged, and a railing, now removed), and still further, the stately avenues long ago planted by Le Nôtre in the centre of the Tuilleries enclosure. There can be nothing more delightful than such a scene on a warm, glaring day when one is surfeited with streets and men, for the quiet is enlivened merely by an occasional nurse-maid and her troop of little ones. But best of all, perhaps, is one of those days of alternate sun and shower which are frequent in Paris even in midsummer. Then the changes of light give each moment a new picture, newly tempting to the painter's hand; and under our protecting awning we can watch the white-capped nurse-maids scurrying before a shower with a little, yet not too much, of that feeling of pleasure in other people's misfortunes which one of their compatriots long ago declared to be a joy dear to all human hearts.

Holiday Notes in Southern France and Northern Italy.—XI.

NICE, a beautifully situated city, is one of the most popular of Mediterranean health-resorts. The mean winter temperature is ten to fifteen degrees Fahr. higher than that of Paris, and the mean summer temperature from five to ten degrees lower. February is the coldest month, and the mean temperature for that month—according to M. Teyseire's published records of twenty years' observations taken with instruments placed outside his window on a fourth floor facing the north-north-east—is forty-six and two-tenths degrees.

The fine avenue of *Eucalyptus globulus* near the railway station at once attracts the attention of the stranger at Nice; here the trees are of considerable height and bulk, and at the time of our visit the smooth polished, white or pink tinted stems looked very picturesque; the bark still hung in long flakes from the larger branches. In many places along the Riviera the *Eucalyptus* present but a sorry appearance; at Nice, on the contrary, they seemed to have soil which exactly suited their requirements. The famous Promenade des Anglais, with its long range of Date Palms, Oleanders, etc., presented nothing remarkable from a garden point of view, nor did the Public Garden, except a group of Pines, clothed with *Wistaria Sinensis*.

The gardens belonging to the King of Würtemberg scarcely repaid the trouble of a visit; as in nearly all the Riviera gardens, there was hardly a green blade of grass to be seen in mid-September, and beds of Zinnias, colored Amaranths, etc., only brought into greater relief the burnt up lawns. A sort of cascade and a piece of rockwork seemed altogether out of place. The only feature of special interest was the fence of tall black and yellow stemmed Bamboos; the first named was

Phyllostachys nigra (*Bambusa nigra* of gardens), with tall, polished, black stems, far higher and thicker than ever they are seen in England, and the other probably a species of *Arundinaria*.

Lambert's nursery is well worth a visit; various species of *Phoenix* were here cultivated in enormous quantities, amongst them *P. tenuis*, *P. Leonensis* (no doubt the south African *P. spinosa*), and *P. Canariensis*. Specimens of *Washingtonia filifera*, in tubs and in the ground, were numerous. Thousands of Camellias and Gardenias were also growing in nursery quarters; a goodly proportion of the latter would be taken up a little later and placed under glass in order to supply the demand for cut flowers during the Nice season. Amongst Ferns, *Pteris tremula* and *P. Cretica* were grown in large quantities, in the open ground, in beds, and also between the rows of Palms, etc. The establishment of Besson Frères is also well worth a visit, Palms and Bamboos being cultivated on a large scale. The fine rows of the Chusan Fan Palm, *Trachycarpus (Chamærops) excelsus*, in the grounds of the Paris Exhibition, mostly came from the nursery just named.

The Castle Hill, in the south-eastern portion of the city, about 320 feet high, is crowned by the ruins of the castle destroyed by the Duke of Berwick at the beginning of the eighteenth century. There are fine grounds—quite a forest of *Pinus Halepensis*, with stems taller and straighter than any we saw elsewhere along the Mediterranean—and Date Palms, Aloes, Agaves, etc., in abundance. Splendid views in all directions are obtained from above the pretty waterfall, which is fed by an aqueduct. During the period of our visit part of the grounds were closed to the public, being occupied by the tents of the soldiers who had been brought there on account of some fever outbreak in their barracks. The long lines of tents and the brightly colored uniforms under the waving Palm-trees lent an additional charm to a wonderfully pretty spot. On the north side of the hill are situated the different cemeteries, our coachman, with charming simplicity, pointing out one which he said belonged to the Protestants—that of the Christians, he added, is further over. It appeared to us that some of the steep slopes bordering the winding carriage drive to the top of the hill might have been clothed with Lentisk, Myrtle and other indigenous plants, which certainly would thrive better and produce a more pleasing effect than the Agaves, which had not soil enough to develop properly.

One of the specialties of Nice is candied Parma violets, which are sold in pretty little round boxes; the petals of Orange-flowers are also candied.

Foreign Correspondence.

London Letter.

HOW to make fruit-culture in England pay has become a problem of some considerable importance within the last two or three years, or, say, from the time when Mr. Gladstone made what is now known as the Great Jam Speech. In addition to the important work done in this direction by the Royal Horticultural Society, there is also the special effort made this year by the Fruiterers' Company, with the great influence of the then Lord Mayor at its back, and we have now a third body called the British Fruit Growers' Association. The objects of this new Association appear to be similar to those of the Royal Horticultural Society in respect to fruit culture, namely, to hold public meetings and conferences in various parts of the country, to collect information, reports, essays, etc., and publish them, to award prizes and certificates; in short, to propagate the gospel of fruit-culture in such a way as shall develop to the fullest the capabilities of the land and its cultivators in the production of hardy fruits. There is a wholesome tendency now toward rigorous selection; bad sorts are to be condemned from the housetops, so that no nurseryman will attempt to grow them; good sorts are to be as loudly recommended, so that none but these shall in future be planted. This is good work. The unwary public are too often persuaded to plant varieties of fruit-trees which are as worthless as Oaks as a source of marketable fruit. There are far too many varieties at present, and if the various societies which have undertaken to push this business succeed in weeding out all worthless kinds, they will have performed good work. What with conferences and reports on fruit exhibited, the public generally know, or ought to know, a great deal more about the merits of different kinds of fruit than they ever did before. Meanwhile, the great bulk of the apples consumed in England during the winter and spring are from America, and being much cheaper than English-grown fruit, they are, as a rule, more palatable than the English

apples offered by the ordinary dealer in winter. Two useful publications devoted to this subject are the cheap edition of Mr. Barron's "Conference Report on Apples," price one and sixpence, a most comprehensive, reliable and well arranged descriptive catalogue, with comments by the author, who is perhaps the first authority on fruits in England. The other publication is Mr. J. Wright's prize essay on "How to Make Fruit-growing Pay." This work was written for the Fruiterers' Company, and is a marvelous shilling's worth of practical information by an eminently practical authority on hardy English fruit.

GRAFTING.—Mr. Parsons' trenchant remarks on this subject are an overwhelming testimony against those ill-advised authorities who set out to convince English gardeners that they were being defrauded by the nurserymen who sold them grafted fruit-trees instead of own-rooted ones. It was difficult to believe that those who condemned grafting of all kinds as a makeshift and a fraud were in earnest. The crusade against grafting in England collapsed suddenly. Probably the Fruit Conferences, held recently, carried conviction to the minds of the few who appear to have thought that they had but to cry out against grafting to get it condemned.

ODONTOGLOSSUMS.—I learn that the cultivation of these plants in America is not so satisfactory as it is in England, owing to the excessive heat of your summers. Have these Orchids been tried in a cool, shaded position out-of-doors during summer? In Germany this treatment is practiced for cool Orchids with considerable success. Most *Odontoglossums* grow well in the open air during summer in England, and Mr. Sander has for several years practiced a method for the cultivation of these plants which may lead to their being grown in beds outside pretty much as we grow the Andean *Begonias* now, namely, plant them outside for the summer, lifting and resting them in-doors in winter. The method referred to is simply planting *Odontoglossums* in beds of peat in low span-roofed houses and treating them as if they were as terrestrial as *Disas*. The bed is formed by two walls supporting slabs of stone, and upon these is placed a layer of drainage, broken soft brick being preferred. About three inches of good rich peat, not fibre merely, but pure peat, is placed upon the drainage, and in this the *Odontoglossums* are planted in rows. Small plants with pseudo-bulbs an inch or so in length produce the first year under this treatment pseudo-bulbs as large and almost as plump as bantams' eggs. Out of what was originally I believe merely a makeshift plan for overcoming pressure of work, Mr. Sander has developed what was described recently by a very eminent botanist as the most astonishing of recent revelations in horticulture. It may, as I have already said, bring us to something not far from "bedding out" for epiphytal Orchids.

PHŒNIX ROEBELINI.—This is a very distinct and pretty little Palm lately introduced from Siam and now in the possession of Messrs. Sander & Co. There is no *Phœnix* like it, the nearest being *P. rupicola*, the most elegant of the species hitherto known. By the side of this, however, *P. Roebelini* is the veriest pigmy, its stems scarcely thicker than a walking stick and almost smooth, and its leaves a foot or so in length, regularly pinnate, the pinnæ as narrow and elegant as those of *Cocos Weddelliana*, shining dark green and plume-like. I have not seen so charming a Palm for a long time. Messrs. Sander hold the entire stock of it. Although introduced only last year, the plants are in good condition and well furnished with healthy foliage. As a table plant this *Phœnix* is certain to become a general favorite.

ERANTHEMUM AURANTIACUM.—The most attractive stove plant in flower at Kew now is this dwarf species of *Eranthemum*. The tallest of the plants is not a foot high, and they are all clothed with gray-green foliage, which forms a suitable foil to the bright scarlet color of the flowers. These are in erect terminal spikes, and whilst the open flowers are scarlet, the buds are bright yellow. A group at Kew is composed of some twenty plants of the *Eranthemum*, arranged under graceful Palms, etc., with a few plants of the rich indigo-blue-berried *Psychotria cyanococca*, whose bunches of fruit suggest miniature bunches of currant-grapes. Both these plants are raised annually from seeds, this method being preferable to cuttings.

EPACRIS.—The value of these plants in winter is appreciated here in all good gardens. A selection of the best varieties is grown for the Kew conservatory, and these, when in flower, are greatly admired. The plants are cut down hard in spring, started in a little warmth, then repotted and allowed to get well rooted in the new soil before being exposed to the outside air. With this treatment they make new shoots from a foot to eighteen inches long, and clothed their whole length with flowers. White, pink, crimson and variegated are the colors

of the flowers. The best varieties are the *Hyacinthiflora* kinds, and those represented by *E. miniata*. Unless they are cut well back and started in a brisk, moist heat in early spring, *Epacris* do not make the growth long enough and ripen it in sufficient time to ensure a good winter display.

New or Little Known Plants.

Rosa foliolosa.

THE *Prairie Rose* of the south-west is one of the more distinctly marked species of the genus as represented in America. In habit it is low, rarely more than a foot in height, spreading by running root-stocks and forming clumps. The stems are slender and leafy, often unarmed; the spines, when present, mostly slender and straight, or nearly so. The leaves are nearly or quite glabrous, pale green and shining above, of seven to eleven small, narrow leaflets, which are acute at both ends, or only acutish at the apex, and simply toothed. The narrow stipules are usually glandular-ciliate, and the stalk of the leaf prickly. The rather large flowers are bright pink and very fragrant, almost always solitary and on quite short pedicels. The depressed-globose hip and the sepals are glandular-hispid, and the outer sepals narrowly lobed.

This little *Rose* was first collected by Thomas Nuttall during his early visit to Arkansas in 1818-20, but was not published until twenty years afterward, when it was described in Torrey and Gray's "Flora of North America" (vol. i., p. 460). Meantime it had been found by Berlandier and Drummond in Texas, and by other collectors. It appears to be confined to the prairie region of Arkansas, the Indian Territory, and northern and central Texas. A nearly allied species (*R. Mexicana*), found by Dr. Palmer in the mountains of Coahuila, Mexico, is the only species known to be native in Mexico proper.

The accompanying figure, on page 101, was drawn by Mr. Faxon from a specimen cultivated at the Arnold Arboretum.

An Analysis of Grafting.

IT is well nigh incredible that any doubt can exist as to the general efficiency or necessity of grafting; and yet the discussions which have run through various journals, mostly foreign, during the last twelvemonth, indicate that the entire utility of the practice is questioned. A careful attention to the discussion reveals the fact that much of it is random, and that generalizations are too often made from local or insufficient facts. We often find that the truth is overlooked or obscured because of the lack of clear-cut definitions and analyses; such is particularly well illustrated in the perennial discussions of "acclimation," concerning which no one knows what his neighbor is talking about.

The practice of grafting—if we use the word to include both grafting and budding, after the manner of the French *greffage*—is so universally and unhesitatingly accepted by nurserymen and growers that no fear of its abandonment need be entertained, no matter what authority may condemn it. But we do need to know more about it, for ever since the absurdities of Pliny and Columella were recorded, it has been a fertile field of misconception and quackery. I do not wish to offer a defense of the practice; none is necessary. But a simple outline of reasons and results, with no attempt to multiply examples beyond the point of mere illustration, may serve a purpose.

It may be said that there are three leading reasons for grafting:

I. To perpetuate a variety. II. To increase ease and speed of propagation. III. To produce some radical change or promote some adaptation in the stock or cion.

The first two statements need no elaboration here, but the third is moot ground, and demands subdivision. These secondary results of grafting, as they may be called, or reciprocal influences of stock and cion, fall readily under the following heads:

1. Grafting may modify the stature of the plant. It is the commonest means of dwarfing plants. We graft the

Fig. 22.—*Rosa foliolosa*.—See page 100.

Pear upon the Quince and the Apple upon the Paradise Apple. This dwarfing usually augments proportionate fruitfulness.

2. Grafting may be made the means of adapting plants to adverse soils. Illustrations are numerous. Many varieties of Plums, when worked on the Peach, thrive in light soils where Plums on their own roots are worthless. Conversely, some Peaches can be adapted to heavy soils by working on the Plum. If dwarf Pears are desired on light soils where the Quince does not thrive, recourse is had to grafting on the Mountain Ash, or some of its allies. In some chalky districts of England the Peach is worked on the Almond. Some Plums can be grown on uncongenial loose soils by working them on the Beach Plum. Professor Budd states, GARDEN AND FOREST for February 12th, that the Gros Pomier Apple is particularly adapted to sandy land and the Tetofsky to low prairie land, and that these stocks are often selected to overcome adversities of soil. Such instances are frequent, and demand greater attention from cultivators.

3. Grafting may be made the means of adapting plants to adverse climate. This may be brought about by either or both of two causes: (a) The early maturation of the stock, causing the cion to ripen better. The Oldenburgh Apple is a favorite stock in severe climates for this reason. The Siberian Crab often has the same influence, although its use is open to serious objection. (b) A slightly imperfect union, causing the cion to mature or ripen early. This fact has been observed in many cases, notably in some instances of Apples upon improved Crabs, and yet the union is often perfect enough, nevertheless, to maintain the plant in a profitable condition for years. There are some adaptations to climate, however, which are not explained by either of the above hypotheses.

4. Grafting may correct a poor habit. All propagators are aware of this fact. The Canada Red Apple is usually top-worked to overcome its weak and straggling habit. The Winter Nelis Pear is a familiar illustration.

5. Grafting is often the means of accelerating fruitfulness—i. e., plants are made to bear at an earlier age. Those who test new orchard-fruits are familiar with this fact. Cions from young trees bear sooner if set in old trees than when set in young ones. This result may be due to the same causes which abbreviate the vigor of plants, as already outlined (see § 3, above). Checking growth induces fruitfulness.

6. Grafting often modifies the season of ripening of fruit. This is brought about by different habits of maturity of wood in the stock and cion. An experiment with Winter Nelis Pear showed that fruit kept longer when grown upon Bloodgood-stocks than when grown upon Flemish Beauty-stocks. The latter stocks in this case evidently completed their growth sooner than the others. Mr. Augur cites an instance in which the Roxbury Russet, grafted upon the Golden Sweet, which is early in ripening, was modified both in flavor and keeping qualities. "Keeping qualities" is but another expression for "season of ripening." These influences are frequent; in fact, they are much commoner, I am convinced, than we are aware.

7. Grafting often augments fruitfulness, largely for the same reasons as discussed in § 3. There are some anomalous instances of increase of fruitfulness, which are difficult of explanation—e. g., some citrus fruits are more productive when grafted upon *Limonia trifoliata* than upon their own roots.

8. Grafting often delays the degeneration of varieties. In various ornamental plants this influence is marked, as compared with plants from cuttings. It is recorded particularly in certain Roses and Camellias.

9. Grafting sometimes increases the size of fruit. The best illustrations of this fact are found in certain Pears when grown upon the Quince—the fruit is often larger than from standard trees.

10. Grafting may result in a modification of color of foliage, flowers or fruit. Assumed influences of this character are frequently recorded, but it is not always possible to determine how much of the modification may be due to soil, climate and treatment. The best instance which I now recall occurred in my own practice. *Prunus Pissardi* gave much more highly colored foliage when grafted upon *Prunus Americana* than upon *P. domestica*. The cions came from the same tree, and the grafted trees stood in the same row. Any acceleration in ripening of fruit (as indicated in § 5) is apt to cause high

color, but the intensification of color in *Prunus Pissardi* was not due to such cause, as the grafts were more vigorous upon *P. Americana*.

11. Grafting may influence the flavor of fruit. There can be no question but that apples often derive acidity from the stock when worked upon the Wild Crab or upon the Siberian Crab. It is commonly supposed that the Angoulême and some other pears are improved in flavor when grown upon the Quince. Downing asserts that some varieties "are considerably improved in flavor" by working upon Quince.

A favorite illustration in support of the reciprocal influences of stock and cion is the fact of transfer of color or variegation by grafting. Darwin called attention to this phenomenon, and used the term "graft-hybrid" to designate the mongrel offspring of certain unions. But this class of phenomena seems to follow inoculation rather than grafting *per se*. The transferable nature of variegation is well known in certain species, but it is entirely inexplicable in the present state of our knowledge; it seems certain, however, that it does not merit attention under a discussion of grafting. So long ago as 1727* variegation was designated a "distemper," which "may be communicated to every plant of the same tribe by inoculating only a single bud." In our own day Morren has called it the "contagion of variegation."

The above outline illustrates the fact that the results of grafting are profoundly modified by conditions. Adverse conditions must give unsatisfactory results, and may lead to a premature denunciation of the whole system of propagation upon the roots of other plants. But, on the other hand, proper conditions and good execution afford abundant and positive proof that grafting—using the word in its broad sense to include budding—is essential to best success in many departments of horticulture.

Garden Flowers and Fruits in Midwinter.

THE mildness of the present winter and the evidences of it as shown by the condition of vegetation in consequence, have been a subject of frequent comment in the horticultural papers of the country. Such winters as this has so far proved in the region about Boston, although not common, are by no means unknown. The winter of 1888-'89, although generally considered very mild, was much colder than this. It is not often that, even in a southern exposure in New England, Snowdrops may be gathered in abundance in January and February, as has been the case this year, or that the sweet-scented single Violets can be found in any number. In a well known garden near Boston a clump of Christmas Roses (*Helleborus*), growing on the south side of some shrubbery, began blooming in November, and in the second week of February still continued to bear in perfection handsome white blossoms. The only protection given was that of a small box with a glass top during the coldest days and nights.

The herbaceous plants, however, play but a very small part in giving interest and ornament to the New England garden in midwinter. It is naturally from the trees and shrubs that the greatest pleasure is to be derived, and the shrubbery that is planted with a judicious selection of those species which retain their foliage or fruits, or which are distinguished by bright colored stems and branches, is certain to lend much brightness to otherwise wintry aspects.

A few shrubs are deservedly valued for their persistent bright fruits, and this winter one or two at the Arboretum are conspicuous by their flowers. The Japanese Witch Hazel (*Hamamelis Japonica*), which is still rare in cultivation, was, on February 5th, almost in full bloom, many of the anthers of the open flowers having shed their pollen; and a week later the plants were in their best and handsomest condition, the small branches bearing a profusion of pretty pale yellow blossoms. Of all early flowering shrubs this may be counted the most valuable, as it will add a new and cheerful feature to our gardens in late winter. The beauty of the flowers does not appear to be at all affected by alternate slight freezings and thawings, and they remain conspicuous for several weeks. This plant is said to become a small tree twenty feet or more in height in its native country, and as it is perfectly hardy here, it may also be expected to attain large size. It may be added that the plants in the Arboretum collection are grafted upon stock of our native Witch Hazel (*H. Virginica*), and appear to thrive well although they grow rather slowly. The *Hamamelis arborea* of European catalogues is a synonym or but a garden form of this Japanese species.

The common European Hazel (*Corylus Avellana*) was found

freely shedding its pollen on February 5th, and, although not a very striking plant at this season, the pollen-bearing catkins are interesting and graceful. A week later the European Alder (*Alnus glutinosa*) was in flower, growing in a sheltered situation beside a running brook. Two closely allied Asiatic Honeysuckles (*Lonicera fragrantissima* and *L. Standishii*) opened a few of their fragrant flowers and ripened anthers early in February. The buds are among the easiest and quickest to develop and expand into blossoms when cut off and taken into the house in winter, and they well repay the trouble, for the fragrance is as sweet as that of violets. *Erica carnea* does best when slightly protected in winter, and if the covering is removed it will be found in a good state of bloom. This is nothing new, as a part of the rosy colored blossoms open in the autumn and the rest in spring. In the same way a few open flowers may be detected on the racemes of *Andromeda floribunda*, and also on *Andromeda Japonica*, in warm situations.

Chief among showy winter fruits would rank the bright red or scarlet of the Mountain Ashes (*Pyrus Americana* and the European *P. aucuparia*), if, in this latitude, the birds did not almost invariably eat them early in the season. As being less liable to be devoured, the next best large-growing plant is the Cranberry-bush (*Viburnum Opulus*), the fruit of which, although very soft and somewhat shriveled, and not in a state to handle, is still quite conspicuous in large pendulous clusters. The scarlet fruit of the Black Alder (*Ilex verticillata*) remains firm and fresh-looking, as does that of the more sparsely fruited *I. laevigata*, but it often appears faded on the side much exposed to the sun.

A number of species of native and foreign wild Roses retain firm-looking and sometimes bright-colored hips throughout the winter, and among them all our native Swamp Rose (*R. Carolina*) is most pleasing and showy, with large corymbs of somewhat bristly dark scarlet fruit. Among Cotoneasters the species known as *C. Simonsii* is the most pleasing winter-fruited one in the Arboretum. The fruit is large, smooth, and bright scarlet in color. The Evergreen Thorn (*Crataegus Pyracantha*) is not as hardy as could be desired in New England, but in some situations gives satisfaction by its evergreen habit and especially by its bright fruit. The Washington Thorn (*Crataegus cordata*) is the only other species here which retains fruit with much color. Much has already been said of the permanent beauty of the fruit of *Berberis Thunbergii*, and its praise is well deserved. Although it is possible that its value as a winter food-providing plant for game birds may be overestimated by some, there is no question of its ornamental character. Its fruit is still the brightest of all the shrubs, and that of no other Barberry approaches it in beauty at this season. The upper berries of the bunches of Coral-berries or Indian Currants (*Symphoricarpos vulgaris*) become sunburned, but most of them retain a bluish red or crimson color; and the conical panicles of fruit of the Sumachs (*Rhus typhina* and *R. glabra*) are red, in some cases having a brownish tinge.

Of black-fruited plants there are several which keep their fruit in a full and unfaded condition. Few of the berries of these remain so bright as that of the common Privet (*Ligustrum vulgare*). There is a yellow-fruited variety of this (var. *xanthocarpa*) which, although not rare, is not often seen. *L. Iboia*, an Asiatic species, bears fruit in greater abundance than the common Privet, and it is also smaller and more loosely set on the panicles. It is black, with a heavy, persistent bluish bloom, and may be considered more interesting than strictly ornamental.

Arnold Arboretum.

J. G. Jack.

Fern Notes.—II.

IN considering Ferns suitable for cool-house culture there is an embarrassment of choice. So many excellent species and varieties are adapted to this treatment that it is impossible to mention more than a very small proportion of them here. Some hints were given last week about a few of the strong-growing sorts, and attention is now called to a limited list of more dwarf species, many of which are quite distinct in character. In establishing a cool-house collection of Ferns a few *Gleichenias* must be chosen, because they are undoubtedly among the handsomest plants of their class; and while they will attain quite a large size, yet they may be kept within reasonable bounds for a number of years, and when well grown always excite the liveliest admiration. Among the species of this genus most suitable for small collections are *Gleichenia dicarpa*, *G. Spelunca*, *G. semi-vestita*, the latter being much like *G. dicarpa* in general appearance, and *G. dichotoma*, *G. rupestris* and *G. Mendelii* are also good; *G. flabellata*, though a

* Bradley, "Ten Practical Discourses Concerning the Four Elements, etc.," 71.

splendid species where fit accommodation can be provided for it, is rather too large for a small fernery. The *Gleichenias* may be increased by division, but in performing this operation it is safest to sever the rhizomes some time before potting them off, so that the pieces may become well rooted before finally removing them from the parent plant.

Hypolepis distans, a well known and very pretty Fern, grows best in the cool fernery, where it soon makes a dense mass of its dark green, finely divided fronds. It is readily increased by division of the rhizomes, the latter being of rapid growth, and with some slight attention after the division is effected the young plants soon become established. *Doryopteris nobilis* and *D. palmata* are both excellent plants, and form a good contrast with some of the finer-leaved Ferns, the bold, strong foliage of *D. nobilis* being very effective. Some of the *Lomarias*, notably *L. ciliata*, *L. gibba*, *L. gibba crispa*, *L. fluviatilis* and *L. nuda*, may be highly commended for the cool fernery,

Another most interesting form is our native "Walking Leaf" (*Camptosorus rhizophyllus*); its indefinite manner of growth from the apex of the frond, from which it produces young plants, is well known, and gives some propriety to the above local designation. A plant of similar characteristics, though perhaps not so widely known, is *Fadyenia prolifera*, a Jamaican Fern of much smaller growth than the *Camptosorus*, though having the same habit in regard to the proliferous nature of the barren fronds. The fertile fronds of *Fadyenia* are of a different character, being simple, erect and about six inches in height, and do not add greatly to the beauty of the plant, as they wither as soon as the spores are ripe.

If the conveniences are at hand for their culture a few of the beautiful Filmy Ferns should find a place in the collection, but unless a well-shaded and moist corner can be given them, it will be found best to grow them in a case, so that their atmosphere may be more easily control-

An Alley in the Tuilleries Garden, Paris.—See page 98.

being not only easily grown and propagated, but also very ornamental in character. The *Lomarias* in general do better under cool treatment than in a stove temperature, besides being less liable to the attacks of thrips and other insects.

Many of the *Nephrodiums* (*Lastreas*) may be counted among hardy Ferns, but there are some that require cool-house cultivation, and among the latter, *N. glabellum*, *N. Sieboldii* and *N. opacum* (or *varium*) are all good sorts, and well worthy of a place even in a small collection. A few of the Fern curiosities, or oddities, can be included in this brief list—for instance, *Polypodium* (*Niphobolus*) *Lingua*, *P. Lingua variegatum* and *P. Lingua corymbiferum*; the leathery-looking, simple fronds of the two first and the much-divided and crested ones of the last are all equally quaint and interesting. These *Polypodiums* are natives of Japan and China, and are chiefly increased by division of the rhizomes.

Such gems as *Iodea superba* and the so-called "Kil-larney Fern" (*Trichomanes radicans*) should not be neglected; and there are many of the *Hymenophyllums* which require similar treatment, though some of the latter are not benefited by being sprinkled overhead as is *Trichomanes radicans*.

Davallia strigosa and *D. hirta cristata* are both handsome species, the latter especially so, and making also a splendid exhibition plant. *Nephrolepis exaltata*, *N. pectinata*, *N. Duffii* and *N. rufescens tripinnatifida* are among the most useful of their genus, being particularly good for planting out on rock-work or for using in baskets. The *Pellæas*, *Nothochlænas*, *Polypodiums* and a multitude of other valuable Ferns cannot now be mentioned, but the intention is only to direct the attention of some inquirer toward this most beautiful and interesting class of plants.

Holmesburg, Pa.

W. H. Taplin.

Begonia manicata.—This is a beautiful old species from Brazil, and, under liberal treatment, one of the most useful in cultivation. It is of moderately free growth, and forms a neat specimen when young. The short, fleshy stems are well clothed with large, oblique leaves of a glossy green color, the footstalks of which are encircled, irregularly, by little hairy scales of a bright reddish color; similar scales appear also on the veins that prominently mark the under side of the leaves, and sometimes on the flower-stalk. The pale pink flowers are small, but very freely borne in erect and large branching panicles; they are exceedingly decorative, and continue in full beauty for a considerable period. The plant may be readily propagated from cuttings—inserted in sandy soil, and placed where they may obtain a moderate amount of bottom-heat, with shade from sunshine till rooted—at any season. During summer they should be shaded from bright sunshine, and kept near the glass, in a house that affords an intermediate temperature, with a moist atmosphere; in winter shading will be unnecessary, and, as that is the flowering season, a somewhat drier atmosphere will then be requisite. The flowering season may be prolonged by the administration of weak liquid manure occasionally. When this season has passed the plants should be cut back slightly, just sufficient to keep them in proper shape, as they are liable to assume a disorderly appearance as they grow old, rested for a brief period, and then reotted.

Habrothamnus elegans.—Ever since its introduction, some fifty years ago, this plant has enjoyed the greatest popularity among the owners of greenhouses in Europe. In this country it is, unfortunately, not quite so popular, but few who see it well grown will rest contented until it has been added to their collections. To see the plant in all its gracefulness and beauty, and to understand that such perfection in culture can be attained with the greatest ease, by no means conveys a complete idea of its meritorious character. Add to these qualities the fact that its beauty continues throughout the entire year, and is most intense during the dull periods of winter and spring; add further the fact that it requires only enough artificial heat to exclude frost, and you will have gained a fair estimate of its utility. It is, in this climate, essentially a greenhouse plant, but it is not at all tender. In its native country of Mexico it grows at an altitude of 4,000 feet, and that fact indicates its comparative hardiness. It is a rather tall-growing shrub, of somewhat slender growth, with dark green, ovate-lanceolate, alternate leaves. The younger branches and the under side of the leaves are pubescent. The tubular flowers, about an inch in length and of a reddish purple color, are freely produced in dense terminal cymes. When the flowers are artificially fertilized, they are succeeded by brilliant red berries, that lend the plant an additional charm. It is seen at its best when planted in a border and trained on a pillar, trellis or the back wall of a lean-to house; in such positions it grows and blooms continuously. When grown in pots it should have abundance of root-room, and an occasional application of liquid manure helps it materially. As the flowering shoots proceed from the previous season's wood, some special care must be exercised in the matter of pruning; these operations, however, are necessary only when the growth becomes too dense or when the plant gets beyond its proper limits. Cuttings, made from firm young shoots, produce roots very readily when inserted in sandy soil during spring or summer, and kept shaded for a few days. Under the more recent name of *Cestrum elegans* this plant is now known to many.

Correspondence.

A So-called "Poisonous" Primrose.

To the Editor of GARDEN AND FOREST:

Sir.—The literature of the alleged poisonous character of the *Primula obconica* commences in GARDEN AND FOREST. In its issue for May 2d, 1888, Doctor James C. White, of the Harvard Medical School and a specialist in skin diseases, states that he was consulted "by one of our largest dealers in flowers, for an inflammation of the skin of the hands and face. The appearance which these parts presented indicated a *dermatitis venenata* of an eczematous type." The florist attributed his trouble to some plant that he had been handling, and suspicion fell upon an *Acacia pubescens* and *Primula obconica*. Some of the florist's assistants were attacked in a similar manner. This skin trouble did not appear until after the plants were brought into the shop and were handled in large quantities. To confirm his suspicions, Doctor White wrote to Professor Goodale, of Harvard, asking if he had ever

known this *Acacia* or this *Primula* to cause skin troubles. Professor Goodale referred the matter to the gardeners at the Botanic Garden, and replied: "Our gardeners say that they have not experienced any trouble from *A. pubescens* or *P. obconica*, but that there is a plant, as yet undetected, which has lately given them a good deal of irritation." Early the following year Dr. White returns to the subject, and in GARDEN AND FOREST of February 20th, 1889, page 94, after referring to the issue of the previous year, he says: "The florist and some of his assistants, whose skin disturbance, therein (last year) described, *dermatitis venenata*, subsided in a short time, and the skin of the three affected persons has remained in a healthy condition until recently. Within the last two or three weeks, however, they have all manifested a recurrence of the same symptoms in about the same degree as last year." *Primula obconica*, one of the suspects of the former year, they now feel assured is the cause of the trouble, as this did not manifest itself until this plant came into the store for sale and had been freely handled in making up floral decorations.

The next evidence comes from Joseph Meehan, of Germantown, Pennsylvania. In GARDEN AND FOREST for March 27th, 1889, Mr. Meehan quotes from a letter of David Cliffe, who, after potting a lot of *Primula obconica*, had his face so swollen that he remained completely blind for a day. This was the severest case yet reported; but it should be stated that Mr. Cliffe was at that time suffering from poisoning by *Euphorbia (Poinsettia) pulcherrima*. Mr. Meehan states that he himself is obliged to avoid contact with Poison Ivy (*Rhus Toxicodendron*), and that the seeds of Oregon Maple (*Acer macrophyllum*) and of Hop Hornbeam (*Ostrya Virginica*) excite itching and inflammation of his hands, while many others who have handled them are not at all affected. These seeds, he states, "are both covered with minute hairs." On June 12th, 1889, GARDEN AND FOREST published a note from Mr. John N. Gerard, of Elizabeth, New Jersey, in which he gives the testimony of a lady who, with several daughters, had experienced most serious inconvenience from handling *Primula obconica*.

English gardeners, as a rule, do not appear to be so susceptible to the irritation caused by *Primula obconica* as do our own, or it may be that the plant grown in the humid climate of Great Britain has its irritating properties less conspicuously developed than in this country.

It is certainly singular that so many should have suspected *Primula obconica* as the cause of annoying skin troubles in themselves and others, without closely examining the plant. A pocket magnifier of moderate power would have revealed such a condition of hairiness that would have suggested further examination with a compound microscope. Both surfaces of the leaves, and especially their margins, show a great abundance and variety of hairs, while the petioles or leaf-stalks are conspicuously hairy, as may be seen without the aid of a glass. To one interested in *Trichomes*, this plant presents material for study in great abundance and variety.

Fig. 23.—Magnified leaf-hairs of *Primula obconica*.

At my request, Mr. John Payne has made a drawing of a fragment of a leaf as it appears under a microscope. This shows the hairs which fringe the margins of the leaves and the calyx-lobes. The large projection in the engraving is one of the teeth upon the margin of the leaf. The surface of a leaf shows some hair like those on the margin, others much shorter and some much longer and weaker. The hairs upon the petioles, so long as to give them a shaggy appearance, present, under the microscope, a great variety in appearance. The hairs are seen to be made of many cells placed end to end. These cells are oblong in outline and diminish slightly in size from the base upward. Frequently one of these cells is much narrower than the one above and the one below it, appearing like a mere stem connecting two parts of the hair. This occurs in no particular portion of the hair, and sometimes there are two constrictions of this kind in the same hair. In many plants the cells have a deposit of silex. This

is the case with *Primula obconica*. If a portion of a leaf, including a portion of the margin, or of the calyx, be simply boiled in nitric acid, the contents of the cells will be removed, leaving a skeleton of the cells in siliceous, and in this *Primula* the hairs are shown to have a silicious skeleton. All traces of the acid being removed by abundant washing, the specimen may be mounted. The large proportion of silica in the hairs of this *Primula* would tend to render them brittle; it would also give them firmness to penetrate the skin when the plant was handled, and, breaking off, they would remain and cause irritation. Has any one examined the skin of an affected person with a magnifier to see if the hairs were remaining in the skin? I did not meet with the only person among my friends whom I know to be affected by the *Primula* until long after the irritation had ceased. Some have likened the effects produced by *Primula obconica* to those of *Rhus Toxicodendron*, the Poison Ivy, but it is a well established fact that many persons are poisoned by *Rhus* without coming in contact with the plant. Merely passing near it or being near a fire where it is being burned is sufficient to cause serious poisoning, indicating that the active principle is volatile. In stinging with Nettles an acrid liquid is said to be injected into the wound made by the stinging hairs. Is the irritation caused upon the skin of those who handle *Primula obconica* any different from what would be caused by a multitude of very fine pine or other splinters? Those who have traveled in the Cactus region of Arizona and neighboring territories are well aware of the irritation that may be and often is caused by the entrance of minute spines into the skin, and do not need to consult a work on *dermatitis venenata* to learn if the Order *Cactaceæ* has furnished, among its eighty-six genera, one or more species which have been known, upon good authority, to produce some degree of inflammation of the skin by contact. The one thing needed in the case of *P. obconica* is a careful investigation as to the character of the disturbance it causes and how it produces it. If, as now appears probable, the hairs with which the plant is abundantly provided are the cause, do these hairs inject any acrid liquid or other substance into the skin? Though contact with the plant is said to produce skin-poisoning, is there any proof of the presence of a poison of any kind as that term is generally understood? What proportion of those who handle the plant are unpleasantly affected? Are persons of a peculiar habit or complexion more susceptible to its effects than others? If these points appear trivial, it should be considered that no plant has been introduced into cultivation in a long time possessing so many elements of popularity as *P. obconica*. It is of great value to the florist, to whom its ready propagation, its abundant and continuous bloom and its adaptability to bouquet and decorative work all commend it. But to the amateur cultivator and lover of plants, whether he cultivate it in the window garden or elsewhere, it is an almost perfect plant. In view of its irritating qualities, some conscientious florists have ceased to offer it for sale, and it promises to pass out of cultivation altogether. With the hope of averting what would be a floral calamity, I plead for investigation, that we may know the extent of the evil. Before it is too late it will be prudent for those microscopists interested in the study of minute plant structure to secure material while it is still to be had.

Passaic, N. J.

George Thurber.

Mocking at Knowledge.

To the Editor of GARDEN AND FOREST:

Sir.—May I claim a little space in which to protest, in the interests of our young folks, against something that I find addressed to them in the pages of a magazine which we have long been accustomed to consider a source of valuable instruction? The department of *Saint Nicholas* called "Jack-in-the-Pulpit" has interested many children in the works of nature, but why should it teach that knowledge of these works destroys the enjoyment of them? In the February number of the magazine a lady who writes of a recent suggestion that it would be well to use the scientific name of *Epigæa repens* instead of the inaccurate *Arbutus*, says: "If we begin to use the scientific names, where shall we stop? The next thing will be to call the delicate Spring Beauty, *Claytonia Virginica*. . . . (By the way, the botanists seem to have had a hobby for calling things after Virginia and Carolina and Canada; when they got tired of using these they named all the rest of the plants after foreign travelers.) But there is worse yet to come. . . . The truth is that the botanists themselves sometimes have two or three names for the same plant. . . . And just think how we have been twitted with

having different common names in different parts of the country! Since I can remember, the dear little Bluets were named *Oldenlandia carulea*. Afterward they were changed back to *Houstonia carulea* by the great Mr. Gray himself. How much simpler just to call the pretty things Bluets! The truth is, my dears, that the Latin names make a herbarium look very learned; and when you collect one I hope you will take great pains to have the plants properly labeled. But what would your poets do with *Houstonia carulea* in their verses? I do not think such terms are suitable for the finer uses of life and literature; so I hope you children all will take pains to learn the common names of the flowers. I only wish you could tell me every one; but perhaps some one will yet make a dictionary of them."

Considering the brevity of this extract, does it not say or suggest a surprising number of misleading things? The reader is led to believe, for instance, that from the standpoint of agreeable sound scientific names, as a class, are greatly inferior to vernacular ones. But is Milkwort prettier than Polygala, or Woad-waxen than Genista, or Tick-trefoil than Desmodium, or False Indigo than Baptisia, or False Mitrewort than Tiarella? Which would a poet prefer to say, Sweet-gum or Liquidambar, Pepperidge or Nyssa, Fetid Marigold or Dysodia, Sneeze-weed or Helenium, Shin-leaf or Pyrola? And would he really object so much even to Claytonia or Houstonia? Of course a list pointing the other way might be made out as easily as this one could be greatly extended. I do not mean to say that all scientific names are musical, or all common ones ugly; only, that to arraign scientific names as a whole from the "æsthetic" standpoint is a foolish act as well as a useless one. It is worse, however, to imply that a hard and fast line can be drawn between the two classes of names. What would the writer call a Dahlia or an Aster or a Nasturtium, a Wistaria, a Fuchsia, a Gerardia, an Azalea or a Chrysanthemum, a Rhododendron, a Sassafras? Would she call Calypso and Arethusa each simply "an Orchid" to avoid scientific terminology—and, by the way, would she find the terminology in this case unfit for poetic or any other "fine" use? How much better it would have been, while quite as easy, to explain that no line can be drawn between the two kinds of names; to show that sometimes the scientific name is perfectly familiar and "common" and often there is no other; that sometimes there is another which is "commoner" in the sense of being English yet is much less familiar even to non-scientific ears; that sometimes there are two which differ only by the change of a letter or so (as with Orchid, Heliotrope, Lily and Gentian); and that often, of course, the vernacular name is so well known and sufficient that even a botanist would not use the scientific one in conversation or ordinary writing unless he were the worst of pedants. And if the author truly desired that the common names of plants should be known, might she not well have counseled an acquaintance with scientific terminology? Do we not all know how difficult it is to find some one to tell us the common names? But we can find them in the "botany books" if we know how to find the scientific name first. "Perhaps some one will still make a dictionary of them;" is not this just what has been done by botanists in their handbooks and what could not be done by any other method than theirs? For how is a plant to be described so its right to a name can be made clear except by means of the terms which scientific writers employ? Any one who has even the most superficial acquaintance with his "Gray's Manual" knows the common names of plants far better, I venture to say, than the most enthusiastic flower-lover who scorns everything "scientific." Of course I need hardly explain here that if a person feels enough interest in plants to wish to recognize different closely related species, then he must, in almost every case, use scientific names or none at all; nor, on the other hand, that it is not always needful to tack the specific to the generic name—that even botanists do not say *Claytonia Virginica* when Claytonia would do as well, or refuse to speak of Houstonia without adding the *carulea*. But these are just the things that ought to be explained when a magazine professes to wish to interest young readers in the works of nature. Would it not have been as interesting to point out why botanical names have been duplicated as to twist the fact as the writer does? And, instead of laughing at the constant reference to Carolina, Canada and Virginia in botanical nomenclature, would it not have been instructive to cite a few historical facts in explanation, and likewise to indicate the biographical significance of the perpetual use of the names of "foreign travelers"? In short, cannot knowledge be made as attractive to children as a "sprightly" mocking at knowledge?

A Mother.

New Haven, Conn.

Esparto Grass.

To the Editor of GARDEN AND FOREST:

Sir.—Can you tell me whether the Spanish Esparto Grass is growing anywhere in the southern States, and whether it can be successfully introduced on the alluvial lands of our southern rivers? I make this inquiry as bearing on the question of the production of a good vegetable fibre for the manufacture of paper.

Hill City, Tenn.

F. G. Hampton.

[We are informed by Dr. Vasey, of the Department of Agriculture, that numerous attempts have been made to grow the Esparto in this country, but without success up to a recent date. Two years ago considerable seed was sent out from the Department, but no reports of success with it have been received. But at Berkeley, California, in the grounds of the California Agricultural College, Dr. Vasey saw last year a long row of this Grass growing very luxuriantly, from which considerable seed had been distributed; so that it appears that the Esparto can be successfully grown in California, and there seems to be no reason why it should not succeed also in the Atlantic states.—Ed.]

Recent Publications.

Plants of Baja California, by Townsend Smith Brandegee. Reprinted from the *Proceedings of the California Academy of Science*, ser. 2, vol. ii., pp. 117, 232; illustrated with twelve plates.

Mr. Brandegee's contribution to our knowledge of the botany of Lower California is one of the most interesting papers on American plants which has recently appeared. Up to the present time very little has been known concerning the botany of the southern part of the Lower California peninsula. Her Majesty's ship "Sulphur," during her voyage of exploration, touched at Cape St. Lucas and at Magdalena Bay in 1839, and the naturalist, Mr. Hinds, made a small collection of plants at these places. Cape St. Lucas was next visited in 1860 by Mr. Zantus, who was the last botanist who visited this region until 1887, when Mr. Walter E. Bryant, the ornithologist, made a small collection of plants from the neighborhood of Magdalena Bay, and Dr. Edward Palmer visited Los Angeles Bay and Muleje. Mr. Brandegee, in the journey which he made through the peninsula last winter, had the opportunity not only to collect again the little known plants of Hinds and Zantus, but to discover several new species, which he describes in this paper.

The peninsula of Lower California, a long, narrow strip of land often not more than sixty miles wide, consists of a mountain range varying in height from two to four thousand feet, with its backbone near the gulf shore and a long gradual slope to the Pacific Ocean. The climate is much warmer on the gulf shore than it is on the Pacific side of the peninsula.

Mr. Brandegee landed in Magdalena Bay in about latitude 24, in January. In the mountains and on the sand-flats about the town of Magdalena Bay 106 species of plants were found; many of these were seen nowhere else, except on the neighboring island of Santa Margarita. No trees grow on these islands with the exception of *Veatchia*, the Elephant-tree, certainly one of the most curious and remarkable of American trees, first detected in this region by Mr. Hinds, but best known by Dr. John A. Veatch's description of the trees, which much later he detected on Cerros Island. *Veatchia* is related to *Rhus*, from which it differs principally in its valvate sepals, accrescent petals, and thin-walled fruit. The flowers, which quite cover the leafless branches during the winter months, are either bright pink or yellowish gray, Mr. Brandegee noticing the different colors on different trees. *Veatchia* is diœcious, but the color of the flowers bears, apparently, no relation to sex. The Elephant-tree attains, sometimes, on the mainland, a height of ten to twenty-five feet, with a trunk one to two feet in diameter. It has low, tortuous, widely-spreading branches, and fascicled leaves one to three inches long, with sessile leaflets, and axillary or more or less large, terminal panicles of minute flowers. It is known locally in Lower California as "Copalquien," and the bark, as is the case with many species of *Rhus*, is used in tanning leather. The ripe fruit has not yet been collected. According to Dr. Veatch, for whom Dr. Gray named the genus, separating it from *Rhus* (the plant was first referred by Bentham to *Schinus*, in his description of the plants collected by Mr.

Hinds on the "Sulphur" voyage), "it derives its name from the elephantine proportions of its sturdy, heavy-looking trunk and branches. The main trunk of a full grown tree will probably average two feet in diameter, the height being a little more and often less than the diameter. The trunk divides into several ponderous branches that shoot off horizontally, and are bent and contracted in grotesque resemblance of the reflexed limbs of a corpulent human being. These huge branches often terminate suddenly in a few short twigs covered with a profusion of red flowers, reminding one of the proboscis of an elephant holding a nosegay. The resemblance is heightened by the peculiar brown, skin-like epidermis that forms the outer bark, which splits and peels off annually, accommodating the increase of growth. The branches of the larger trees often shoot out to a horizontal distance of twenty feet from the trunk, thus covering an area of forty feet in diameter. Smaller subordinate limbs spring upward from the upper side of the large boughs, and in this way give a neat oval appearance to the outline of the tree. When loaded with its bright red flowers the effect is strikingly beautiful, particularly where hundreds of the trees stand near each other, intertwining their huge boughs and forbidding ingress to the mysterious space they cover and protect. The young tree looks a good deal like a huge radish protruding from the ground with but a slight root and a few twig-like branches expanding from the top."

Mr. Brandegee, from Magdalena, went up the lagoon to San Gregoria, where a number of new plants were found. One of the most interesting, perhaps, is the new *Ipomœa*, first detected on Magdalena Island, and for which the name of *I. Ficama* is proposed. It is a woody species climbing about over shrubs and producing large white flowers. The chief interest of this plant, however, is found in its roots, which "bear tubers that are much sought for on account of their fine flavor and watery juice. One weighing six pounds is said to have been found, and traditions of a ten-pounder are extant; but the largest seen weighed two or three pounds and they are usually much smaller. These tubers must grow very fast during the rainy and spring season, for their location, often three feet or more from the base of the stems, is discovered by the growth cracking the soil. New stems never spring from them and their use to the parent plant is uncertain; perhaps it is to store up moisture to be drawn during the dry season. These round tubers or "Jicamas" are always eaten raw and resemble in taste a turnip somewhat sweetened. Wherever the plant grows, near plantations or along trails, numerous little hollows may be seen around the plants at distances varying from two to four feet, showing the places from which the tubers have been dug."

From San Gregoria our traveler proceeded to Comondu, where two weeks were given to a careful exploration of the flora, and then, with a pack train and guides, was begun the principal journey, which carried the party through the centre of the peninsula for a distance of nearly five hundred miles, over a dry, desolate, rocky and almost uninhabited region, finally landing them, at the end of a weary march of two months, at San Quintin, two degrees south of San Diego. A fine new *Agave*, for which Mr. Brandegee proposes the name of *A. sobria*, was the most conspicuous plant on the high *mesas* about Comondu. It is described as ten feet high, with thick radical leaves and a panicle of five hundred dark yellow flowers. After leaving Comondu no great change was observed in the flora for several days. *Rhus laurina*, a common tree or shrub covering large areas in southern California and in the northern part of the peninsula, was first seen near San Jose de Gracia, no doubt at the southern limit of its distribution; and near here were several large forests of *Cereus Pringlei* (see GARDEN AND FOREST, ii., 6). For a new arborescent *Yucca* Mr. Brandegee proposes the name of *Yucca valeda*. It attains the height of fifteen or twenty feet, with trunks eight inches to two feet or more in diameter, growing in clumps and branching from the base. The leaves are thin, smooth, flexible, six to nine inches long and only a half to three-quarters of an inch wide, the margins dividing into slender white threads. The panicle of flowers is very short, only about a foot long and somewhat pubescent. The flowers are creamy white, two to two and a half inches broad, on peduncles nearly as long as the segments of the perianth, which are broadly lanceolate. A photograph (plate xi.) represents a wide-spreading specimen of this interesting plant, which, near Patrocinia, forms forests miles in extent; the trees, Mr. Brandegee remarks, being in general appearance strikingly like those of *Y. brevifolia* of the Mohave Desert, though the trunks are less covered with the old reflexed leaves. The old Catholic Mission at San Ignacio, embalmed in a forest of Date Palms, seemed

like an oasis in the desert. At San Julio, a cañon eight hundred feet deep, with walls apparently perpendicular, was explored, and here was found, no doubt at its southern limit, the Holly Cherry of California (*Prunus ilicifolia*), with the entire leaves which characterize the form peculiar to Santa Cruz Island. Veatchia re-appeared at San Pabalo on the mountains, and afterwards was often encountered as far north as San Fernando. "The trail from San Ignacio passed," Mr. Brandegee tells us, "over high mesas, down and up deep rocky cañons all the way to San Pablo and mostly over sandy plains from there to Calmulli. A great change in vegetation took place in this vicinity, and many of the characteristic plants at the south, that were abundant on the sandy plains about Cañon Grande, have now disappeared, and thenceforward, until we reached the Gulf coast at the Soda Springs of Calamujuet, the flora resembled that so familiar to us in southern California." Such Arizona trees as *Dalea spinosa*, *Olneya Tesota*, *Chilopsis saligna*, form a large part of the vegetation at Calamujuet, although Veatchia was still the most conspicuous object; "the trees, covered with pink blossoms, forming a perfect blaze of color which could be seen plainly miles away." "Annuals, both at Magdalena Bay and San Gregoria, bloom in January and February, and by April have for the most part disappeared. Many shrubs ripen their fruit in January, although many species of Cactus and some perennials do not flower until April or May. The most noticeable feature of the flora over the whole region visited by Mr. Brandegee is the *Cactaceæ*, which often form forests and impassable thickets, and brighten the landscape in May with their showy flowers. Agaves are common and cover the ground in some localities. Leguminous trees are, on the whole, the most common and furnish most of the wood used by the inhabitants. The bruised stems of *Cereus gumosus* are used for stupefying fish. The leaves of *Lippia barbata*, a shrubby species, are employed in cooking to flavor meat, while those of another shrubby species, *L. fastigiata*, under the name of "Damania," are made into a sort of tea.

Among other interesting plants detected by Mr. Brandegee are *Polygala apopetala* (plate iii.), a shrubby species; a new *Horsfordia*, a new *Spæralcea*, with slender, herbaceous stems, eight feet high, and a new *Gossypium*, which Mr. Brandegee dedicates to Dr. H. W. Harkness, President of the California Academy of Science, "as a tribute to his efforts in furthering the exploration of Lower California;" a new *Bursera*, several *Daleas* and *Hosackias*, an arborescent *Lysiloma*, whose bark is used for tanning hides used to hold the wine of the country, which thus receives a disagreeable flavor from the bark of this tree. Several new *Cereus* and *Opuntias*, and an interesting *Aralia* (*A. Scopulorum*, plate viii.), a shrubby species, four to ten feet high, with petioled leaves, with three to seven leaflets, and compound inflorescence, are described. A new genus, *Alvordia*, in *Compositæ*, in honor of William Alvord, the President of the Bank of California, "in recognition of his well known unceasing interest in and efforts for the furtherance of botanical knowledge," is proposed for a suffrutescent perennial. *Gilia gloriosa* (plate xi.) is a shrubby species, densely branched, and forming round clumps, three or four feet high, about which Mr. Brandegee remarks that "it will be difficult to exaggerate its beauty as it is seen growing in rounded masses, with the many-shaded large blossoms crowded toward the end of the branches." Unfortunately, no seed could be obtained of this plant, which appears to be very local, having been observed only at one place—Ubi.

To Mr. Brandegee's paper is appended an account of his plants of the *Euphorbia* family, from the pen of Dr. C. F. Millsbaugh, and a list of fungi, by H. W. Harkness.

Recent Plant Portraits.

MONTBRETIA CROCOSMÆFLORA, *Revue Horticole*, January 16th; a group of some of the newer varieties, obtained by M. Lemoine, of Nancy.

SOLANUM MACRANTHUM, *Gardeners' Chronicle*, January 18th; Mr. W. Botting Hemsley throws considerable new light upon this fine species, at one time supposed to be a native of southern China, but now shown to be identical with a specimen collected by Mr. Pearce on the Amatala River, at an elevation of from four thousand to five thousand feet, in Bolivia. *Solanum macranthum* becomes a tree fifteen to twenty feet high, called, at Hong-Kong, where it appears to have been long cultivated and where it flowers throughout the year, the Potato-tree. Carrière pointed out, some time ago, that it was cultivated at Cairo, where it succeeds admirably and forms an ornamental tree of the first order. In France it is used in so-called sub-tropical gardening—that is, young

plants started under glass in winter are planted in the open ground at the beginning of summer, and attain, under good cultivation, a considerable size before frost. It is one of the species with large, lobed leaves, with scattered prickles, and it has great clusters of flowers, each three inches in diameter, and varying in color from white to an intense violet-blue, with large, bright yellow anthers. *S. macranthum* may be expected to succeed in some parts of California and possibly in the southern Atlantic States.

DARLINGTONIA CALIFORNICA, *Gardeners' Chronicle*, January 18th; the portrait of a beautifully grown plant from the Mount Merion gardens near Dublin, the largest pitcher measuring three feet nine inches in length. This is probably one of the very best specimens of a peculiar plant, difficult to manage in cultivation, which has been produced.

LÆLIA GOULDIANA, *Gardeners' Chronicle*, February 8th, a figure of this handsome winter-blooming species, from a plant which produced ten spikes and over forty of its bright rosy crimson flowers at Christmas-time in Sir Trevor Lawrence's garden. *Lælia Gouldiana* was an introduction of Messrs. Siebrecht & Wadley, of this city, and was named for Mr. Jay Gould.

Exhibitions.

Orchids at the Eden Musée.

THE fourth annual exhibition of Orchids, which is now in progress under the direction of Messrs. Siebrecht & Wadley, has been more numerously attended than any of its predecessors; indeed, the throngs on some days have been so dense that an inspection of the flowers was almost impossible. And the visitors found much that was worthy of study and admiration. As usual, the larger portion of the plants came from the Rose Hill Nurseries, but the contributions from the collections of Mrs. F. Goodrich, of Mr. W. S. Kimball, of Mr. J. Eyerman, of Easton, Pennsylvania, and Mr. Frederick Mau added greatly to the value and interest of the display. Indeed, the group of hybrid *Cypripediums* which Mr. Kimball sent on from Rochester and which nestled modestly among the Ferns on a little circular table in the centre of the room, was to many connoisseurs the most attractive part of the show. Here was *C. Winnianum* between its parent plants, *C. Druryi* and *C. villosum*. Near these was the delicate *C. Measuresianum*, with *C. euryandrum majus*, *C. Argus*, Kimball's variety, *C. calophyllum striatum* and many more which are only found where the most rare and costly *Cypripediums* are collected. Another group of cut flowers sent by Mr. Kimball included such fine varieties as *Cattleya Trianae Backhousiana*, the exceedingly rare *Cattleya amethystoglossa alba*, *Dendrobium nobile elegans*, *D. oculatum fimbriatum*, two long spikes of *Odontoglossum Coradinei pallidum*, *Zygopetalum rostratum*, the bright orange-scarlet *Ada aurantiaca*, the curious terrestrial Orchid, *Stenorhynchus speciosus*, with its coral-red spike and beautifully spotted foliage, the bright red *Epidendrum radicans*, spikes of *Schomburgkia undulata*, and many more of almost equal interest.

On the side of the hall beyond Mr. Kimball's flowers were twenty-five plants of *Cattleya Trianae* exhibited by Mr. Frederick Mau, of Weehawken, New Jersey, which deserve special mention. Of course, the *Cattleyas* of this species were more abundant than any others, but Mr. Mau's plants had been selected as the choice of thousands, and in richness of color and firmness of texture they made a striking group. An unnamed and distinct *Odontoglossum*, in the way of *O. cristatellum*, was another noteworthy plant in this collection.

Mrs. Goodrich and Mr. John Eyerman contributed many fine flowers, among them the best example of the white flowered *Cattleya Trianae*, and a beautifully colored *C. Bogotensis*, a flower rarely seen. The gem of the collection of Mr. De Forest, of Summit, New Jersey, was an immense plant of *C. Trianae alba*, two feet in diameter.

The tables in the body of the room were usually arranged with large Palms rising from their centres, with the Orchids grouped about them in masses of *Adiantum cuneatum* and *A. Farleyense*. A superb *Seaforthia elegans* towered above Mr. Kimball's *Cypripediums*, a tall *Chamærops* graced another table, a *Rhapis* rose from a third, and in the anteroom was a magnificent *Encephalartos*, twelve feet through. All these were furnished by Messrs. Siebrecht & Wadley, as were the other plants used for general decoration. *Ericas* were abundantly used, and the stage was particularly attractive, surrounded by a double row of Heaths and Azaleas, behind a line of *Adiantums* and an edging of *Lycopodium*.

Among the Orchids from the Rose Hill collection were masses of finely grown *Phalaenopsis*, many *Oncidiums*, including several good specimens of *O. Papilio*, a striking

group of the bold, rich colored *Cattleya Percivalliana*, Odonoglossums by the score, including a good example of *O. Ræzii album*, well grown specimens of *Vanda suavis*, *Miltonia vexillaria*, *Cattleya intermedia superba* and many more. A unique *Cypripedium* is attracting much attention. It resembles *C. calurum*, but is much darker—a deep purplish red. The origin of the plant has not been made known.

The exhibition will remain open all the week.

Notes.

In former years the prices of cut flowers have invariably fallen from thirty to fifty per cent. on the arrival of Lent, but this year there has been no decline whatever in prices in this city.

Among the floral designs at the funeral of Her Majesty the Empress Augusta was a cross five feet long and more than two feet wide, made of White Lilacs, White Camellias, Lilies-of-the-Valley and *Cypripedium Spectabile*.

Nature announces the death, at Malta, of Dr. Gulia, Professor of Botany, Hygiene and Forensic Medicine in the University of Valletta. Dr. Gulia is known by his "Flora of Malta," an enlarged edition of which he left unprinted, and which is to be brought out by his son.

Mr. F. H. Horsford, of Charlotte, Vermont, and Mr. Edward Gillett, of Southwick, Massachusetts, have combined their nurseries of wild flowers and hardy herbaceous plants, at the latter place, where, under the firm name of Gillett & Horsford, their united business will be conducted hereafter.

In Leicestershire, England, a lawyer recently brought suit against a farmer, complaining that the latter allowed Thistles to grow in a certain field to such an extent that the plaintiff's garden, some 300 yards away, was seriously injured by their seeds. Damages were awarded to the amount of three guineas.

We read in the recent issue of *Science* that the result of the Prang canvass for a popular expression with regard to the national flower gives seventy per cent. of all the votes for the Golden-rod, sixteen per cent. for the Mayflower, and fourteen per cent. divided among the Daisy, the Mountain Laurel, Dandelion, Sunflower and various other plants.

According to Dr. Draper's calculations, the weather in this vicinity has been more abnormal this season than for seventy years past. The high temperature of November, of December or of January had been matched or overmatched during these seventy years, but taken together their average temperature was higher than that of any corresponding three.

Between the 21st of last October and the 7th of January George Klehm, of Arlington Heights, Chicago, cut 20,700 Violets in a greenhouse, devoted to this flower, which measures 125 feet by ten. H. Dale, of Brampton, Ontario, writes to the *American Florist* that between November 1st and January 17th he picked 10,550 Violets from a bench 100 feet long and only four feet wide.

Mr. Vogel, a timber-land explorer, recently returned from north-western Manitoba, reports, in one of the "limits" looked over by him, "150,000,000 feet of White Spruce (*Picea alba*) log-timber killed by fire during the past season. This fire not only killed the trees, but burned the bark and most of the branches from the trunks, and about a foot of the moss and vegetable deposits from the surface of the ground."

Our London correspondent called attention to the fact that difficulty had been experienced in England in the cultivation of the handsome Bornean Pitcher-plant, *Nepenthes Rajah*, and that it was not successfully managed until it was removed from the hot-house to one with a lower temperature. It is worth recording that this plant is and has been flourishing for several years in the stove-house in Mr. F. L. Ames' garden, where it is grown with a general collection of hot-house plants, including a large number of *Nepenthes*, and where it forms pitchers freely, and is just now passing out of flower. No trouble has ever been found in managing the plant, whose living pitchers Mr. Court, an expert in the cultivation of *Nepenthes* saw at North Easton for the first time.

The January issue of the *Illustrirte Gartenzeitung*, of Vienna, names 108 "new roses for 1890." Seventy-three of them come from France and only five from this country—Rosalie and Marshall P. Wilder are credited to Messrs. Ellwanger & Barry, Dinsmore to Mr. Henderson, and The Queen and White Pearl simply to America. But on another page very high praise is given to Rainbow, a sport from Papa Gontier, introduced by Mr. J. H. Sievers, of San Francisco, which is called "the newest Rose." In the same number facts are cited with

reference to the enormous Rose-growing establishment of the Messrs. Strauss in Washington, and are contrasted with the statement that when at a recent ball in Vienna it was decided to make extensive use of fine Roses, the city itself could supply but a very few, and Paris, Nice and Cannes had to be laid under contribution.

Mention was made in our last issue of a hybrid Rose raised at the Arnold Arboretum by crossing the Japanese *Rosa multiflora* with pollen of General Jacqueminot. Another of the seedlings produced by this cross has now flowered, and proves to be quite distinct from the plant which flowered first. The second seedling resembles its Japanese parent in foliage, and in its long, stout stems with rather remote, stout, hooked spines. The flowers are produced in clusters like those of *R. multiflora*. They are, however, semi-double, bright pink, and fragrant, although rather less so than the flowers produced on the first plant. These seedlings seem to show that Mr. Dawson has hit upon the right means to secure a race of hardy polyantha Roses with bright colored fragrant flowers.

A writer in a French periodical gives a curious account of the introduction of *Nicotiana colossea*, a relative of the Tobacco-plant of commerce, which was one of the finest ornamental plants shown at the recent Paris Exhibition. Several years ago he sold some Brazilian Orchids to a lady, whose gardener took the trouble to plant the trimmings and dust, as well as the Orchids themselves, in the greenhouse. A number of seeds germinated, and certain promising young seedlings, transplanted to the open air, proved to be *Nicotiana colossea*. Its leaves measure forty inches in length by twenty-two in breadth, are purplish and erect when young, but afterward a dark, shining green and spreading. The plant grows to be ten feet or more in height in the open air, where, in France, it has not bloomed. It is an annual in this situation, but a perennial in the greenhouse.

An idea of the wealth of the city of Paris in works of sculpture may be gathered from the fact that sixty-four figures and groups decorate the Tuilleries gardens, while the Luxembourg gardens contain sixty-seven, in addition to a number of decorative statues by unknown artists, which were brought from the park at Sceaux, and to the colossal fountain in the Avenue de l'Observatoire, for which Fremiet and Carpeaux supplied the figures. Almost all these works are originals by French sculptors, although some are fine copies from the antique. Even in the little Parc Monceau there are seven excellent statues, chief among them the "Sower" of Chapu, and the "Harvester" of Gaudet. As a rule, the placing of the statues has been as judicious as their selection, although occasionally they stand in the middle of a large lawn, where they can be well seen from one point of view only, and where they injure the breadth and repose of the lawn itself.

In "Humboldt" for December, 1889, is an interesting statement of the amounts expended by the Prussian State Forestry Commission to control the ravages of forest insects only. In 1884-85 were spent 200,550 marks; in 1885-86 were spent 171,404 marks; in 1886-87 were spent 191,645 marks. Of these sums the control of *Hylobius abietis* alone took from 107,200 to 109,300 marks. In commenting on these facts, *Entomologica Americana* remarks that the sums are suggestive, and yet the amount was absolutely necessary for the prevention of serious damage. Even with these sums, and the trained officials to apply them, the success in lessening the ravages was not satisfactory. It was not possible to do more than keep the pests in check. The destruction of the Cockchafer in the larval state is also still in the experimental stage, and the results are not satisfactory. The complaints in other parts of the empire of damage by white grubs are even greater than they are in Prussia, and some practical remedy would be a boon of inestimable value.

Catalogues Received.

CHARLES A. MCBRIDE, 64½ West Bay Street, Jacksonville, Fla.; Fruit and Ornamental Trees, Shrubs, Roses, etc.—JOHN R. & A. MURDOCH, 508 Smithfield Street, Pittsburgh, Pa.; Vegetable and Flower Seeds, Plants, etc.—PITCHER & MANDA, United States Nurseries, Short Hills, N. J.; Hardy Perennials, Aquatics, Alpines, Orchids, Ferns and Small Shrubs, Chrysanthemums, etc.—RUMSEY & Co., Ltd., Seneca Falls, N. Y.; Spraying Pumps.—T. H. SPAULDING, Orange, N. Wasted Effort in Forest-Reform.

IN a letter which will be found on another page of this issue, Mr. Binney states that much effort toward forest-reform has been wasted. By this he means that if the desultory, volunteer work of all persons who have attempted in their own individual way to put some check upon the useless destruction of forests had been organized and concentrated, much more would have been accomplished than has been gained up to the present time. It is true also that organization not only makes work effective, but what is of still greater importance, it offers opportunity for work to many willing persons who otherwise could find nothing to do. At the present time there are several bills before Congress, each of which is honestly intended to protect and preserve the forests on the public domain. Senator Sherman, for example, has offered one which calls for a commission, consisting of the Chief Engineer of the Army, the Chief Signal Officer, the Secretary of Agriculture and the Secretary of the Smithsonian Institute, to assume a certain control over the public forests, and Senator Hale has introduced another measure similar to the one advocated two years ago by the Forestry Congress. Mr. Dunnell has charge of a third, of which we have before spoken. There is little doubt that if the authors of all these bills and the forces which are behind them should unite upon some common policy, the chances of success would be much greater than are the chances for either measure now.

The efforts of the men who show an interest in the Adirondack forests are even more divided and scattering. The Forest Commission has certain bills of its own to pass. The Governor writes a special message recommending a State Park, which project is condemned by the committee to whom it is referred. The Speaker of the House presents another bill for an Adirondack Park, and certain physicians of this city have organized still another scheme for a sanitarium, which they propose to push forward without regard to any other interests. Unfortunately there is a suspicion that more than one of these schemes is only patriotic on its face, and the appearance of public spirit is only a disguise to conceal selfish purposes. It is rumored that behind one large park scheme stands a great iron-master, who has stripped the timber from thousands of acres, and now that

the land is no longer useful for his purpose, he is eager to sell it to the state. Another Adirondack Park scheme is conceived, according to the statement of one of its projectors, primarily for the diversion of a few, and not for the health and happiness of the many. There can be no question that if there was an active association of all the men in the state who have an intelligent and unselfish interest in preserving what is left of the North Woods—an association with means to employ salaried agents to devote their time to these questions and give the proper direction to public opinion—the future of the Adirondacks would be more hopeful. As the case now is, reputable newspapers have been betrayed into advocating measures which mean ruin for the forest and robbery for the state. If sagacious men were paid to look after the interests of the forests, in Albany and elsewhere, just as other interests are cared for by trusts and business unions of one sort or another, persons who really desire to protect the forests could be warned, at least, against advocating measures which have been framed to defeat the very object which they pretend to promote.

Now, it is very true that we have no guarantee that forest associations will act wisely. They may fall under injudicious management; they may try to accomplish impossibilities or to secure even pernicious legislation. But, after all, they must be judged as other human agencies are judged, and if wise men are dissatisfied with their administration the true remedy is to secure a better executive force. Certain it is that the approved modern way of carrying on any reform is through men who are employed to devote themselves to the business systematically and exclusively; to use all legitimate means of instruction and influence through the press, and at the Capitol; to watch over the forests, if forest-reform is their object, with an interest as vigilant, at least, as that which is exercised by those who are organizing plans for their destruction. It is true that a half dozen wealthy men might unite to employ such agents; but the natural way, even for such men, is to work through larger associations, adding their liberal contributions to the mites of those who can afford to give no more.

The state organizations are doing much indispensable work, but we wish especially to state here our belief that the National Forestry Association is worthy of the confidence and support of those who are concerned about the forests of the country. It has a definite object in view, which is to secure the appointment of a properly equipped Commission to examine the government forests and report the best method to preserve and utilize them, insisting, meanwhile, that all forest-land shall be withdrawn from sale and entry until such method is adopted. This object ought to commend itself to all thoughtful Americans, and therefore, in our opinion, a large increase in the membership of the Association is in every way desirable, both as a means for raising funds and for the influence which comes from the power of numbers. Aid extended to this Association will not be effort wasted.

Mr. Charles Eliot suggests in another column the formation of associations for the purpose of holding and protecting for the public benefit pieces of ground like that covered by the Waverly Oaks; of special beauty or of special interest. Such an association, as we pointed out last year, exists already in the town of Cassanovia, in this state, and the beautiful falls of the Chittenango are preserved by its efforts in all their wild picturesqueness. Spots of unusual natural beauty, or of real historical interest, may still be found near many of our cities, and there can be no doubt that such places should be preserved for the people who seem destined, in ever increasing numbers, to throng American cities. The work of securing these bits of scenery, as well as open spaces or play-grounds in what is still the country, but which sooner or later will be covered over with bricks and mortar, cannot be undertaken too soon or pushed too energetically. Such pieces of ground can often be secured now with a comparatively small outlay in money, and the necessary authority for holding

them can doubtless be obtained from other state governments as it has from that of this state. Contributions of money would flow into the treasury of such an association as soon as people became convinced that it was managed judiciously and for the best interests of the public, and the only real difficulty in carrying out Mr. Eliot's excellent suggestion will be found in securing persons of the necessary attainments for such work with the leisure requisite for the organization and management of such a trust. Good men and women for such work are difficult to find always, and the most fitting have generally their hands more than full with public and private duties.

We have occasionally suggested that perhaps the projectors of immense storage reservoirs for purposes of irrigation neglected to take into account the danger which threatened life and property from these great volumes of imprisoned water. The reply to these cautions has always been that the problem was a simple one to engineers who understood the physical conditions in the arid regions, and that American skill could be trusted with the construction of the needed dams, which could be made absolutely safe. The bursting of the great Walnut Grove reservoir in Arizona, however, seems to justify all the warnings that have been sounded. This work has been spoken of as a masterpiece of engineering skill. It has been illustrated in the press as one of the wonders of the country, and was pronounced perfectly able to withstand any possible pressure from floods. And yet it gave way at the very first serious onset of the waters. The horrors of Johnstown were not repeated simply because there were not so many people in the track of the torrent. It is a misfortune that Major Powell is less zealous to protect the natural reservoirs furnished by the mountain forests than he is to construct artificial ones, which certainly are less safe, and which may be less effective than he imagines.

The Art of Gardening—An Historical Sketch.

XVIII.—The Mahometans in Persia.

HAVING glanced at India as it was before the advent of its Mahometan conquerors, we may now turn back to Persia, where these conquerors were to learn their skill in the art of gardening. Persia is exceptionally interesting to the student of history in any of its branches because it has so often refreshed its power under the rule of a new dynasty or a new race. From the time of Cyrus to our own, whatever the name and the faith of its rulers, the individuality of Persia has never been wiped out, and national tastes have persisted and have influenced both the East and the West. In the sixth century of our era not even Justinian's capital on the Bosphorus was more splendid than Ctesiphon, the capital of the Sassanid sovereigns of Persia, and their love for pleasure-grounds is embalmed in anecdotes that are repeated in every school history. Poetical and religious writings still more clearly reflect the national passion for gardens. St. John pictures a purely architectural paradise as the home of the Christian blessed. But the seventh heaven reserved for the followers of Zoroaster, as described by writers of the Sassanid period, was to be a garden with paths of polished gold, filled with flowers and fruits and odors and with pleasure-houses of diamond and pearl; and one special spot is described at length. Here, in white and golden robes, on thrones of gold and silver, will sit the geni of water, of fire and of plants, and with them the souls of "governors and officials, who have not failed in good works, who have dug fountains and canals, built aqueducts, established inns and resting-places for weary wanderers, laid out gardens for the pleasure of the poor, and not impiously hewn down trees and plants; who have guarded the sacred fire and followed the religion of Zoroaster."*

Into the luxurious and intellectual land of Persia broke the rude, conquering, proselytizing Arab shortly after the death of Mahomet in the seventh century. Here, for the first time, he came in contact with a highly developed civilization. Here he quickly absorbed its lessons, and, gradually amalgamating with the native Persian, developed the arts and sciences which he found in bud; and hence all he had learned

was carried westward over half the ancient empire of Rome and eastward much farther than the Roman had ever gone.

There was no united kingdom of Persia for centuries after the first Mahometan inroad. But this fact only served to increase the splendor of the land at large, each district having its lordly ruler and flourishing under his lavish hand.† When we speak of Bagdad in the time of Haroun-al-Raschid, when we read of it in the "Arabian Nights" or the poems of Persian singers, we think of a city of gardens, shadowy with Cypress, Poplar and Plane, plashing with innumerable fountains and rivulets, sweet with a thousand odors, brilliant with a myriad flowers by day and a million twinkling lamps by night. Bagdad without its gardens, or Damascus, or Shiraz, or Ispahan, would be like Rome without its hills, like Venice without its waves.

The western Asiatic, with his strong feeling for architectural beauty, never made the mistake of surrounding stately buildings with grounds of a purely "natural" character. His urban gardens, as we can be sure even from the fanciful descriptions in the "Arabian Nights," and as will be shown when we speak of the gardens of the Arabs in Europe, were formal in arrangement, with marble walks and benches, regular avenues, and a multitude of fountains and pavilions. Shade and coolness were the things he cared for most, and the odor of flowers was as much prized as their beauty. But the semi-poetic, semi-fantastic cast of the west Asiatic mind leads it to appreciate picturesqueness and variety as well as symmetry; and whenever it has been inspired by romantic landscape forms, it has reproduced their charm in appropriate situations. A mediæval writer, Abu Ishak Ibrahim, called El Istachri, in his "Book of the Roads of the Countries" (which treats of the whole of Islam, but especially of Persia), tells of five thousand country-houses or "castles," some standing in the neighborhood of towns, but some deep in the mountains. Half a dozen centuries make as little change, very often, in the tastes and customs of oriental as does half a century in those of occidental nations. Modern Persia is but the degenerate child of mediæval Persia; and thus, when later on we shall read of the aspect of the Persian country home of to-day, we shall realize that in mediæval years a romantic wildness, carefully simulated by art, distinguished its grounds when the natural character of the landscape permitted.

The planting of shade-trees along streets and highways was sedulously practiced in mediæval Persia. Teheran was called "the city of Planes," from its embowered streets, and the Plane was everywhere the favorite tree for such purposes.‡

What we call Saracenic architecture was born under the Mahometan rulers of Persia, and was based on ancient Persian elements. So, too, was the gardening art that accompanied it as it spread to the Atlantic and the Ganges. There were no such masters of the art of gardening as the Mahometan shahs and khalifs during the whole thousand years which divided the eclipse of classic architecture from its renaissance in modern Italy. While Gothic architecture was so splendidly developing in the north, gardening art, as we have seen, scarcely there deserved the name. But the two arts flourished hand and hand in the Mahometan south, and, indeed, the work of the mediæval Mahometan gardener has, in some respects, never been surpassed. Is it not interesting to know that in this case, as in the case of ancient Athens and Rome, the first impulse, the first teaching, came from Persia?§

All along the north coast of Africa and over many of the southern shores of Europe the Mahometan conquerors gradually spread, at first destroying like very Goths, but soon repairing the relics of ancient beauty which they found, or creating new beauty on newly chosen sites. In the fourth century, as has been told, Belisarius found the Vandals luxuriating in a thousand villas and gardens in those parts of Africa where at first the Phœnician settlers and then the

† Jaeger, in his "Gartenkunst und Gaerten," compares the influence upon national culture exerted by these local capitals to that exerted by the many small courts of Germany during the seventeenth and eighteenth centuries. But it should be remembered that in the middle ages there were no other countries where science and art were similarly fostered. "Their splendid palaces," says Hallam, "History of the Middle Ages," of the khalifs of Bagdad, "their numerous guards, their treasures of gold and silver, the populousness and wealth of their cities, formed a striking contrast to the rudeness and poverty of the western nations in the same age. In their court, learning, which the first Moslems had despised as unwelcome, or rejected as profane, was held in honor."

‡ Benjamin: "Persia and the Persians." Colonel Yule, in the notes to his edition of Marco Polo's "Travels," gives an interesting account of some famous Plane-trees in Persia: and the Venetian adventurer's own story of the "Old Man of the Mountain" and his "paradise" well illustrates the national delight in gardens.

§ The inborn oriental love for gardens shows, of course, in Mahomet's own descriptions of paradise; but, although the imagination of the Arab had been fired by the achievements of others, his artistic instincts found but slight chance to express themselves until he came under Persian influence.

* Justi, "Geschichte des alten Persiens."

colonists of Rome had luxuriated before them. Here in the eighth century the new race of garden-lovers found the relics of many pleasure-grounds and utilized for their rehabilitation the huge aqueducts and tanks that had been built by Phœnician and patched by Roman hands—works that even to-day exist, although now amid wholly desert surroundings.

On the little island of Mascali, off the coast of Catania, lay a Saracenic garden often visited by the Crusaders, and described with the enthusiasm of men fresh from the rude, inhospitable north. The garden called "Zisa," which the Saracens laid out near Palermo, in Sicily, excited admiration even in the sixteenth century. It had a great central building with colonnades and pavilions surrounding a marble basin; another larger piece of water encircling a kiosk with a gilt cupola and rich stucco and mosaic decorations; and walks canopied with trellises leading to a park two miles in circumference, which was probably a preserve for curious animals. The garden of the "Moorish palace" of Navello, near Salerno, still shows remains of terraces and plantations which "delight the eye of the connoisseur." ||

New York City.

M. G. Van Rensselaer.

Holiday Notes in Southern France and Northern Italy.—XII.

ANTIBES, the Antipolis of the ancient Greeks, is a small, lively seaport of about 6,000 inhabitants, beautifully situated on a promontory commanding magnificent views of the Mediterranean and the Alpes Maritimes. The only relics of antiquity it can now boast are a couple of towers; these, however, as well as the strong fortifications built by Vauban, we pass over without remark, for the real object of our pilgrimage to Antibes was to visit the famous gardens of the Villa Thuret, so ably managed by M. Naudin. After the death of M. Thuret, the late proprietor, the gardens became the property of the French nation, and they are now used for experiments in the open-air cultivation of tropical and sub-tropical plants. M. Naudin has made a special study of the species of Eucalyptus which are now grown in such large numbers in the Mediterranean region, and, as far as Europe is concerned, he is the authority for this large, difficult and very variable genus.

The Villa itself is clothed with such creepers as Bougainvillea, Tecoma and other showy plants which in England we have to cultivate in a warm house; behind it is a fine grove of Stone Pines. An entire number of GARDEN AND FOREST would not more than provide space for a catalogue of all the remarkable plants at Antibes, and but a very small proportion can therefore be enumerated now. Palms are well represented by remarkably fine examples. The finest specimen of *Fubaa spectabilis* we had ever seen has a huge trunk about two yards through at the base. *Sabal Blackburniana*—of which there is a grand plant in the Palm-stove at Kew—is here in excellent health, as is also *S. Havanensis* and some other species. *Livistona australis* and *Cocos australis*, the latter bearing a plentiful crop of fruit, are also especially worthy of mention.

Erigeron mucronatum—or, as it used to be called in English gardens, *Vittadenia trilobata*—made a very neat and pretty border along some of the walks. In sunny open spots Mesembryanthemums were very effectively used in a similar way, among them the large yellow-flowered *M. edule*—the Hot-tentot Fig of the Cape of Good Hope.

Many remarkable conifers are to be seen at Antibes. Here for the first time we had the pleasure of meeting with the Chinese Weeping Cypress, *Cupressus funebris*, in its adult condition, exactly similar in appearance to the species as figured by Fortune in his "Travels." In Britain—at any rate, in the neighborhood of London—this interesting plant, though growing freely enough for a time, gets injured badly by frost or killed outright every ten or a dozen years. Side by side with the Cedar of Lebanon, the Deodar, *Abies Pinsapo*, etc., which thrive so well with us, such sub-tropical species as *Pinus Canariensis*—here a large, handsome tree with rich red bark, the Mexican Cypress, *C. Benthamiana*—a fine tree with spray of the richest green, *C. pendula glauca*—a species with very glaucous leaves, said to be of Indian origin, the Bunya-Bunya Pine of Queensland—*Araucaria Bidwilli*—were noted in luxuriant health and beauty. *Abies Cilicica*, too, which can hardly be made to exist in the open at Kew, is, at Antibes, a handsome pyramidal tree.

Succulents are largely grown, and all the species previously mentioned in former chapters of my holiday notes, together with many others, are to be seen in the Jardin Thuret. Bes-

||Jaeger: "Gartenkunst und Gaerten."

chorneria yuccoides—or, at any rate, a plant so named; for it differs from the Kew specimens in being distinctly filamentose—has a stem seven or eight feet in height, surmounted by a crown of huge leaves. One of the finest of all the Yuccas, the Mexican *Y. filifera*—so well figured in GARDEN AND FOREST, vol. i., page 78—formed a conspicuous feature on one of the lawns; a group of five huge stems, some fifteen feet in height, produced a fine effect.

A Mexican Berberis, *B. trifoliata*, with its dense growth and rigid spiny leaves, is one of the most conspicuous of the dwarf shrubs. A thorough contrast to this is the Eastern Australian *Citriobatus multiflorus*, with its small, round, deep green leaves and spines (abortive branches) twice as long as the foliage; this peculiar member of the Pittosporum family forms an excellent fence.

Away from the Villa Thuret, toward the end of the promontory, the Lentisk, Myrtle, Smilax and other indigenous plants, with here and there various Mesembryanthemums, etc., which have become naturalized, thrive in wild luxuriance among the rocks facing the sea, where in times of storm they are dashed with salt spray.

Foreign Correspondence.

London Letter.

AN event of very great importance to English horticulture is the decision of the Royal Horticultural Society to build for itself in a central position in London an exhibition hall, offices and library. The sum of £40,000 is to be raised in a manner both novel and commendable—i. e., the fellows of the Society and their friends are to lend the money, which is to be invested by trustees partly in first-class securities yielding three and a half per cent. interest, which will be required to pay ground rent, and partly in the new buildings. About £3,000 was promised at the general meeting on Tuesday last. The money is to be repaid without interest by the annual redemption of bonds.

This scheme was unfolded to the fellows by Baron Schroöder, a most liberal patron of horticulture, a member of the Council of the Horticultural Society, and one of the most successful bankers in London. The interest and zeal of the Baron in this business are looked upon as being an assurance of its success. In his speech the Baron commented on the very marked development in the last year or so of a taste for gardening and flowers among the business men of England and especially of London. The Society has only to place itself at the service of these thousands of recruits to horticulture to secure their fellowship and support. The Royal Agricultural Society numbers about 10,000 fellows and spends thousands of pounds annually in the promotion of agriculture in England. Horticulture, which is almost as important an industry as agriculture, is in need of the same unity and assistance, and the Royal Horticultural Society is the body on which the work of organization to this end naturally devolves. At present English horticulture is almost a house divided against itself. In no country in the world is horticulture of so much importance as in England, and yet until now nothing has been done to collect its forces and unite its followers under one banner. Baron Schroöder's scheme is a great step toward a remedy for this state of things. In a few years we shall wonder how the present want of a home and head for gardening and its followers was tolerated so long.

The plants shown last Tuesday included some interesting novelties. Large groups of Lenten Lilies (Hellebores) in variety, some poor, some exceptionally good; of Persian Cyclamens, early Daffodils and other herbaceous plants, were sent by various nurserymen. Messrs. Lee, of Hammersmith, once famous for Australian plants, now chiefly for hardy trees and shrubs, exhibited a tastefully arranged group of ornamental-leaved and bright-berried shrubs, such as could be employed for the embellishment of the out-door garden in winter. Aucubas, rich in berries and color, standard Ivies, Laurustinus, Osmanthus, Pernettyas, many kinds of conifers, Euonymus, etc., all remarkable either for variegation or elegance of habit—these were arranged in a sort of parterre garden. A very elegant Yucca, perfectly hardy and as graceful as a Cordyline, was represented by many beautiful examples. It is called *Y. plicata*, apparently a garden name. This plant is certain to prove of great value in countries where the Australian Cordylines cannot be grown out-of-doors, as it is an excellent substitute for them and as easy to manage as any garden Yucca. Of the plants known to me it is most like *Y. Peacockii*, a supposed Mexican species, described by Mr. Baker about ten years ago.

As is usually the case at these meetings, the Orchids were well represented. A strong spike of flowers of *Phalanopsis F. L. Ames*, recently figured in GARDEN AND FOREST, was exhibited by Messrs. Veitch, who also sent examples of *Cypripedium Lathamianum*, a handsome hybrid from *C. Spicerianum* and *C. villosum*, and especially interesting as being the first known instance of precisely the same result having been obtained by crossing two species both ways. As a rule, the difference between the progeny of two parents crossed differently is well marked and often wide. *C. Rothschildianum* was exhibited in flower, the raceme bearing three very fine blooms. It was named *C. Elliotianum*, but a comparison between it and the figure in the *Botanical Magazine* proved the name erroneous. There are good reasons for believing that the difference between *C. Rothschildianum* and *C. Elliotianum* is merely varietal, and that in many collections the same plant does duty for both. A handsome variety of *C. cardinale* named Vanner's variety was remarkably like your native Moccasin flower, *C. spectabile*.

Odontoglossum ramosissimum, introduced in 1871, remains a rare plant, although it is distinct and handsome. The flowers are two inches across, full, pale rose-purple, showing white here and there, wavy, the lip narrow and reflexed. A strong plant, bearing a stout, many-flowered panicle, was shown and received a first-class certificate. This species is very distinct and unusual in color amongst *Odontoglossums*. Some wonderful specimens of *Calogyne cristata*, *Cypripedium insigne*, *Lycaste Skinneri* and other well known Orchids were shown as examples of exceptional culture. The *Cypripedium* was a grand mass of foliage, and bore over a hundred expanded flowers. It was in a twelve-inch pot.

Greenhouse Rhododendrons were shown by Messrs. Veitch, amongst them being some beautiful deep colored hybrids recently obtained from *R. multicolor*, a Sumatran species introduced about five years ago, and distributed by Messrs. Veitch under the name of *R. Curtisii*. The charm of these new hybrids is in their dwarf, bushy, compact habit, small, dark green leaves and the brilliancy of their flower-colors. The Rhododendrons from the mountains of the Malaya regions are proving as plastic and prolific of beautiful garden plants, under the manipulation of Messrs. Veitch, as did the Andean Begonias in their hands about ten years ago. I believe I have already related in your paper the success met with at Kew in the cultivation of this class of Rhododendron in the large winter garden, where the temperature in winter sinks to forty-five degrees. It is quite clear that whilst they grow and flower freely when treated as stove or warm house plants, almost every one of the Malayan race of Rhododendrons may be successfully managed in a cold house. They require a rich peat soil and plenty of moisture at all times.

Washingtonia filifera.—The article by Mr. Parish on the Palms of California is a most interesting and valuable contribution to our knowledge of some of the most useful of European garden Palms. What he states with regard to Washingtonias and their names is fully borne out by observation here. I do not believe there is even a varietal difference between the plants called *W. filifera* and *W. robusta*. This conclusion was arrived at after seeing great numbers of these plants on the Riviera, where Washingtonias are very common in gardens. In a report on the garden plants of the Riviera which I wrote for the Kew *Bulletin* in December last the following particulars of these plants were given. I quote them as interesting when placed by the side of Mr. Parish's statistics re the distribution and dimensions of Washingtonias in California:

"Equaling the Canarian Phoenix (*P. Canariensis*) in its extensive use, in its proportions and in rapidity of growth, is the Washingtonia. The growth made by this Palm on the Riviera is astonishing, and it appears to thrive equally well in all the stations. There must be hundreds of thousands of plants of it in the gardens and nurseries visited, and the prices asked indicate that there is a great demand for it. . . . It does not appear to have been introduced into European gardens before 1875, and is therefore a comparatively new Palm. Notwithstanding this, there are some very large specimens of it on the Riviera, where it is called Brahea or Pritchardia. I could not see any characters in the plants pointed out as *W. robusta* to distinguish them from *W. filifera*; the reddish hue of the petiole at the base appears to be the principal difference.

"At Villa Valetta, Cannes, on a sloping lawn in front of the house, is a grove of about sixty magnificent specimens of this Palm, to me a marvelous sight. Most of these plants had huge onion-shaped stems, ten feet in circumference at the base and about ten feet high, some even higher. The crown of foliage was twenty feet through, and was composed of from

fifty to eighty leaves, each with a stout armed petiole five feet long, a blade four and a half feet across, and ornamented with numerous white, hanging filaments a foot long. I was assured that the largest of these plants was not more than twelve years old, and from the date of the introduction of the species this cannot be far from correct. At Nice I saw a specimen the stem of which was fifteen feet high. In exposed situations within a few yards of the sea this Palm is perfectly healthy."

The dead leaves are not allowed to remain on the stem, consequently the appearance of this Palm on the Riviera is very different from that of the wild plants as described by Mr. Parish. The Riviera gardeners manure their Palms most liberally and in dry weather they are kept well supplied with water.

Mr. Parish does not mention *W. Sonora*, a new species described by Dr. Sereno Watson, who sent a few seeds of it to Kew in 1888, from which we have now about a dozen good plants. At present their most striking character is the deep crimson-brown of the petioles and stem.

London.

W. Watson.

Hypericum Kalmianum.

Hypericum Kalmianum was one of the first of the American Saint John's Words described, having been discovered by the Swedish botanist, Kalm, whose name was bestowed upon it by Linnæus, probably at Niagara Falls, which he visited in 1750. It is a straggling bush, growing to a height of two or three feet, with rather contorted four-angled stems, covered with thin, exfoliating reddish bark, slender two-edged branchlets, and crowded oblanceolate pale leaves one to two inches long. The flowers are bright yellow, an inch across, and begin to open early in July. The pods are ovate and five-celled, a character which best distinguishes this species from the nearly allied *H. prolificum* of the middle and western states, the pods of which are three-celled.

Hypericum Kalmianum (see page 113) is rather a rare plant, being confined to lake and river-cliffs from the Falls of Niagara, where it is found on Goat Island, to the northern Lakes. Like the other shrubby Hypericums, it is an excellent garden plant, although less showy in flower than some of the other species. They all bloom at midsummer, when few shrubs are in flower; and grow easily, flower profusely, and are not particular about the treatment they receive.

New or Little Known Plants.

A Giant African Aloe.

A. Bainesii.

THE picture on page 115 is taken from a photograph made in Grahamstown, South Africa, and represents one of the most remarkable of the many arborescent species of Aloe found on the African continent. *A. Bainesii* was first described by Mr. Thiselton Dyer, the present Director at Kew, in the *Gardeners' Chronicle* in 1874, and it was named in honor of its discoverer, Thomas Baines, the African explorer, whose book, "Explorations in South-west Africa," is a most interesting account of his journey from Walvisch Bay to the Victoria Falls, which he accomplished in 1861-62.

The discovery of the Aloe is referred to in this book at pages 33, 34. Baines was at the time about a hundred miles east of Walvisch Bay, and near the Swa-kop River, when he noticed "what seemed like an ordinary Dragon-tree or Baobab, a familiar object to the South African traveler. On approaching to sketch it more minutely I found that it was a gigantic Aloe. Kneeling on the ground so as to bring my arms low enough to embrace the solid trunk, I found its circumference to be nearly twelve feet. Above this it divides into five stems, each of which at nearly the same height sent forth branches as thick as my arm, of uniform size, even to the top, where they were crowned each by the well known star of Aloe-leaves, and adorned with three or more magnificent spikes of yellow flowers. The stems were smooth and round; but at the base the bark appeared

to burst and curl off in large flakes, as if their veneers of fine satin-wood had warped off the foundation they were laid on. The effect of this magnificent crown of leaves and flowers, perfectly rounded in contour, and fifteen or more feet in diameter, and as many from the ground, contrasted

time a missionary in Kaffirland sent to Professor Macowan a description of an arborescent Aloe, which was considered distinct from *A. Bainesii*, and described under the name of *A. Barberæ*. It has been proved, however, since that time, that the two plants are identical.

Fig. 24.—*Hypericum Kalmianum*.—See page 112.

with the sterile rocks on which it grew, was lovely in the extreme."

The same traveler found this same species on the opposite side of Africa—namely, in northern Natal—and he forwarded a living branch of it to Kew, from which a plant now in the Kew collection was obtained. About the same

The illustration represents three plants which had been brought about twenty-five years ago from the Transkei, in Kaffirland, by Commandant Bowker, and presented to Sir Walter Currie, who at that time was residing in Grahams-town. They are at the present time in magnificent health, the dimensions of the largest being as follows: Height,

twenty-four feet; diameter of head, twenty feet; girth of stem at base, nine feet; girth eight feet from the ground, seven and a half feet; length of leaves, two and a half feet.

There is a beautiful specimen of this Aloe on one of the lawns in the Botanical Gardens at Grahamstown. The frequent branching, smoothness and roundness of the stems and remarkable habit of bark-peeling, similar to what occurs in the Oriental Plane—these characters, as well as the gigantic stature of full-grown plants, place this species of Aloe among the most remarkable of the many vegetable monsters found in Africa.

The practical value of this picture is in its presenting the features of a plant which may be grown in temperate and sub-tropical countries, and which is one of the easiest of Aloes to cultivate. In Grahamstown slight frosts are not infrequent, whilst the summer temperature and other climatic conditions are about the same as those of New York. In the south of France many species of Aloe are grown in the open, and their flowers make a magnificent display. It is easy to imagine the fine effect that might be produced in many gardens of your southern states by groups of such plants as these arborescent Aloes. In dry countries, or in poor, rocky localities, the African Aloes would be quite at home.

Kew.

W. Watson.

Cattleya labiata Warscewiczii, Autumn-flowering.

Cattleya labiata Warscewiczii, or *Cattleya gigas*, as it is often called, is a well known summer-flowering form. According to Messrs. Veitch (in their Manual) it generally flowers in the Orchid-houses of Europe in July and August, but it is not unusual for flowers to appear in May and June. A letter just received affords evidence that it may flower later as well as earlier than the usual period. The editor of GARDEN AND FOREST writes: "I enclose for your consideration a *Cattleya* flower and a sketch of the same. It is from a plant purchased by Mr. F. L. Ames several years ago from Low & Co. as an imported *C. Mendellii*. You see, however, that the flower is quite distinct, or, at least, Orchid people here say that it is, and, moreover, it flowers always late in November and in December, a peculiarity which gives this form great garden value. The leaves are short and broad like those of *C. Mendellii*. It is certainly a very showy and beautiful thing." The last remark I fully endorse, for the dried flower is seven and three-quarters inches in diameter, and the color very brilliant, so that when fresh it must have been a superb thing. On comparison it seems to me, botanically, identical with the form named above, well known to be the largest and most distinct of the *Labiata* forms, and one which, even when dried, can hardly be mistaken for any other. The sepals and petals are of a bright rosy mauve, the front lobe of the lip rich crimson-purple, and behind this are situated two large bright yellow blotches, separated by the reddish-purple disc. If the autumn-flowering habit should prove constant, as would appear from the letter, it is certainly a very valuable acquisition. That the plant should have been imported as the variety *Mendellii* is perhaps not remarkable, seeing that both are natives of the eastern Cordillera of New Granada, though I am not sure whether both have been found growing intermixed. It is just possible that Messrs. Low & Co. have some memoranda on the subject of the particular importation in which it appeared. Unfortunately such information is not often easy to obtain, especially when the subject is such a handsome plant as is the present one.

Herbarium, Kew.

R. A. Rolfe.

Since the above was written I have received a note from Mr. William Robinson, gardener to Mr. Ames, stating that the habit is remarkably like that of the variety *Mendellii*, and that it has maintained the same character for five years consecutively, flowering in November and December, after which it commences to make its growth, which is matured some four or five months before its flowering season, exactly as in *C. labiata vera*.

Cultural Department.

The Watermelon.

THIS fruit grows in hot countries generally, but has not so great a range of climate as the Cantaloupe. It appears to be divided into two distinct classes—one adapted to very hot localities, and the other not able to bear well more than a limited degree of heat. Those from the tropics grow larger and

finer in this latitude, and the melons of Spain and Italy do as well here as in those countries, although but few of them are worth introducing. Watermelons from milder climates than ours will grow in New Jersey soil, but are never inviting in flavor. When cut open they crack before the knife with a sort of explosive sound; are often white-fleshed, and seldom of a rich red; they are deficient in sweetness, and the flesh is sometimes tough. I have found one desirable Russian melon, one Spanish, three Italian, one Cappadocian, one Japanese and one African, in a large number of varieties tested from many countries. All of the vines I have examined were of the same peculiar, well known character of leaf, except one from Liberrian seeds, which had a large, solid, ovate-pointed leaf, set close to the stem, and growing right and left alternately, and parallel with the ground.

Watermelons are long, semi-long, oval and round; their seeds are black, brown, white, red, buff, gray and mottled. All of these colors may be found in very large, medium and very small seeds. As a general rule, a large melon bears large seeds, and *vice versa*, but there are exceptions. White-rinded melons may have very small black seeds, as in the Russian, or may be large and white, or buff with a brown edge. The most delicious melons, as a rule, are thin-rinded, and pink or dark red in flesh. Such Watermelons do not bear transportation well, the breakage in some being up to fifteen per cent. In interior colors we also find white, yellow and amber-colored.

Many foreign melons have very tiny seeds, and some of the fruits may be readily eaten by one person. Orange melons, or those having an easily separated rind, are said to be produced of very small size in Bulgaria and the extreme south of Italy, but have not yet been grown here.

Watermelons with very small seeds, down to half an inch in length, are quite abundant in some countries, especially southern Russia, Armenia and Sicily. In Persia the favorite is called a "black Watermelon," from its very dark green color, as we have the "black Italian"; it is very thin-rinded, and is easily broken in transportation. The Japanese produce a melon of a long apple-shape, having very tiny seeds and a thin rind, that grows well in our climate, and has been considered an excellent variety by private growers, but its small size has prevented its acceptance by the trade. Such fruits make good hybrids with larger varieties.

Large, tough-rinded, symmetrical melons of fine quality, which keep and carry well, are now produced in enormous quantities in our Southern States, and some may be carried in good condition to Europe or kept from the last of September to Christmas. As an article of diet the Watermelon requires a better digestive power in the eater than is required for the Cantaloupe, and some dyspeptics who consume the latter with comfort, do not dare to more than taste the former.

This country now produces a greater variety of large Watermelons than ever before, and they can be grown to a heavier weight. In 1800 there were melons in the Philadelphia market that measured forty-five inches in girth; but they did not grow them in our country of 108, 111 and 125 pounds until within a few years, when new varieties reached these weights, in favorable seasons and localities.

In the olden time, our Watermelons were chiefly long, oval, dark green or striped, and had large black or brown seeds. Spanish seeds produced our first thin-rinded melons; but these soon changed in character under the work of the bees. Spanish melons are still grown, but are altered in form over those produced by imported seeds.

The French have a peculiar way of keeping a melon; the fruit is cut with a long stem, which is coiled up and then buried under brown sugar to keep it from drying up by exposure to the air.—*From a paper read before the Pennsylvania Horticultural Society by Robert P. Harris, M.D.*

Reinwardtias.

THESE plants must be classed among the best that can be grown for the decoration of a warm greenhouse during winter. There are three species, all of which are found in a wild state on East Indian mountains. Regarding the species, Sir Joseph Hooker says there is good ground for believing the three to be mere varieties of a common type, and the two in cultivation would certainly confirm that opinion. These are *R. tetragynum* and *R. trigynum*—the latter perhaps better known as *Linum trigynum*. They are dwarf shrubs, of free growth and neat habit, with leaves of a pleasing dark green color, and large bright flowers, which, in the former, are of a delicate sulphur color, and in the latter of a more distinct yellow. At the outset it must be understood that these plants can be grown satisfactorily only by those who command a

greenhouse in which an intermediate night temperature (*i. e.*, a temperature of about fifty degrees) is maintained during the winter months. Many attempt their cultivation in cooler houses, and, being unsuccessful, the plants are regarded as worthless. Where proper attention is given to their requirements, on the contrary, they are most useful and attractive. Young plants are the most satisfactory, and they may be readily obtained from cuttings. The points of robust shoots will be found most suitable for cuttings; and, early in April, they should be inserted in pots containing sandy compost, then placed in moderate bottom-heat, kept close and shaded until rooted. Shading will then be unnecessary; air may be admitted daily;

the plants. The syringe must be used three times a day, so that insects may be kept in check and the surrounding atmosphere kept in that moist condition which appears so essential to the health of the plants. Less shading will suffice as the weather grows cooler, and they will then require protection at night. About the latter end of September they may be removed to the house again, where the atmosphere should be kept moist until they show signs of flowering. The moisture in the atmosphere and use of the syringe may then be gradually decreased, and, finally, the syringing discontinued when the first blooms expand. Attention to watering is now all that is required to ensure a continuous display of bloom through-

Fig. 25.—A Giant African Aloe (*A. Bainesii*).—See page 112.

and, to induce bushy growth, the extreme point of each cutting should be pinched out. When new growths appear on the cuttings they may be potted-off into three-inch pots—using a mixture of loam, peat, leaf-mould and sand, in equal parts—and grown-on in a warm house, in which a moist atmosphere prevails. Five-inch pots will be found large enough to admit the full development of such plants, and when well established in these they may be removed to a cold-frame. Here the pots should be plunged to the rim in ashes, or some such material, and arranged so that the plants will be as near the glass as possible. In summer the lights will not be needed, except to protect the plants from heavy or too frequent rainstorms. Shading from bright sunshine will be beneficial, but it must be removed at night and during dull weather, and it should never interfere with the free circulation of air about

out the winter. Where it is desirable to obtain larger specimens the plants thus obtained may be grown on during the following season. Flowering will be discontinued early in February, and the plants may then be removed to a sunny house and rested slightly for a few weeks. They may be cut back about the beginning of April, and, a few days after, again placed in a growing atmosphere. When growth has commenced, turn them out of the pots, reduce the balls slightly and repot in five-inch pots. On being returned to the house they must be syringed overhead regularly, but great care should be exercised in the application of water to the roots until the plants get well started. Pinch the leading shoots when the young roots reach the sides of the pots, and about two weeks after pinching, the plants that have made good progress may be potted-on into seven-inch pots, and removed

to a cold-frame when established, and afterward treated as they were the previous year. In this way old plants may be grown on from year to year, and gradually increased in size; but it should not be forgotten that they rarely give as much satisfaction as young plants raised from cuttings. As the flowers soon drop, they are almost valueless when cut; and even upon the plants they remain in perfection for only a comparatively short period; but they are speedily replaced by others, and so the plants remain attractive.

Cambridge, Mass.

M. Barker.

Orchard Experiences.—II.

THE distance at which our various fruit-trees should stand in an orchard is a subject yet worth discussion, notwithstanding the voluminous teachings of our books and journals. For old-fashioned, slow orcharding, where standards in grass are expected to come into profitable bearing in from twelve to fifteen years, nothing is better for Apples than the old rule of forty feet each way. I would apply the same limit to Pears, notwithstanding the upright growth of so many varieties of this fruit. The habit of growth is of small importance in the premises. An upright habit gives more air and light between the trees, but this does not justify closer planting, when we remember that an upright tree may be quite as productive as a spreading one. If space is given to ensure sufficient feeding ground, the upright-growing tree, equally productive, requires as much root-room as those of a spreading growth. In these wide-planted, grassy orchards, from which the hay is annually removed, and to which only occasional top-dressings are given, we can only hope for biennial crops. Tillage and manuring is required to make annual producers. Even these will not ensure yearly crops with all varieties.

Under a different system, early-bearing sorts being used, quicker and better results may be obtained by much closer planting, provided the fertilization and tillage are commensurate. With these early-bearers, planted twenty feet each way, much more prompt and profitable results may be had. The fruit on young trees, well cared for, is large and handsome, selling at high prices, and a large quantity may be obtained in the ten or twelve years before it is necessary to thin out the orchard. The close setting is a protection to both trees and fruit; but an orchardist adopting this method must be prompt and resolute in thinning out his trees. When the crop reaches about five or six bushels to the tree it is time to remove every alternate row; and in about five years more we must take out alternate trees in the remaining rows. We then have left our twenty-five standard trees to the acre, and have taken off, meantime, enough choice fruit to much more than cover every expense. Those who adopt this method sometimes prefer to have the trees which are to be removed something else than Apples—either Plums and Cherries, or dwarf Pears. In my latitude I find the early-bearing, short-lived Russian summer Apples, especially the Yellow Transparent, best. They begin bearing quite freely within two or three years, and have seen their best days by the time it is necessary to remove them. Between the trees, one way, Currants, Gooseberries and Black-caps thrive, with no apparent detriment to the trees. This is a great deal better than the old way, especially to those who have reached middle age before beginning to plant, or to those who need an immediate income from the land. For the first five or six years Dwarf Beans and Peas, or Strawberries, may be successfully grown in the young orchard. Liberal manuring and clean culture are essential.

Newport, Vt.

T. H. Hoskins.

Seed-growing is now the order of the day, and it is as fascinating to some of us as it is important. Success or failure often turns on very slight and apparently unimportant points, and as hints are always in order, I wish to note that in case of fine seeds, especially of Begonias, I find that success depends much on sowing very thinly. The point of a small knife-blade will hold enough seed for the sowing of a pan six inches square, and more is worse than waste, for if the soil is covered with visible patches of seed it seems to be fatal to their germination. From such a quantity of seed, sown thinly, I have known 600 plants to be pricked off, while in over-seeded pans plants appear very sparsely. The culture of Begonias from seed offers no difficulties. It is sometimes stated that young seedlings are inclined to "go off," but this must be from badly aired house, as under proper treatment there are few less "miffy" things.

Doronicum Harper Crewe, besides being a good plant for the cool house, as noted by Mr. Thorpe, is a first rate garden plant, perfectly hardy, and probably the earliest-flowering hardy herbaceous yellow Composite. It is a plant of distinct aspect, and the best of the family, about two feet in height, with numerous

flowers, as described. The foliage in the open is of the light, tender green so grateful in the spring garden. In its habit of growth it resembles the Oriental Poppy, the foliage dying down after bloom is over, to start again in the fall, a valuable trait in a spring-blooming plant, since by planting something of later growth near it, one has practically two crops from the same space, always a point of importance, and especially so in a small garden.

Elizabeth, N. J.

J. N. Gerard.

Correspondence.

The Uses and Claims of Forestry Associations.

To the Editor of GARDEN AND FOREST:

Sir.—There has been for some years past in America a marked and constantly increasing interest in, and perception of the needs of, forestry, or, to use a broader word, forest-reform—*i. e.*, the adoption of some adequate check on forest-destruction and some rational system of forest-preservation. The growth of the forest-reform idea is shown in the conversation of the people one meets, in the columns of the newspapers, in the existence of your own journal, devoted in part to the subject, and also in the formation of a few forestry associations, of whose work, indeed, it is itself partly a result. Yet though thousands are aware of the evils we now suffer from forest-destruction, and of their necessary continuance and increase unless our treatment of forests be radically changed, practically nothing is done. The tree-planting in the prairie states has been chiefly for shade or wind-breaks, not for timber supply, or to protect the sources of streams, which usually rise in the hills, where the axe is known, but not the spade. In the east some enthusiast may have here and there reclaimed a few waste acres by planting, and taught a good object lesson thereby; but of real forest-reform, the systematic retention of forests where they are needed, especially on mountain slopes, their cutting with a view to future growth, and their protection from fire, there has been practically nothing, east or west. In New York, the appointment of three gentlemen to protect the forestry interests of the state and the sources of the Hudson and Mohawk, without pay, would be laughable were it not too serious; yet this, and the slight check on fire thus brought about, is more than almost any other state has done. Common sense bills have been presented, both in Congress and state legislatures, but they have never come out of the committee rooms alive, and the prospect, except possibly in New York, is not much more encouraging now than it was ten years ago.

In short, it must be confessed not only that, in the vast majority of cases, the interest really felt in forest-preservation has not resulted in any actual work, but even that a great deal of honest and conscientious effort has been wasted. The reason, to my mind, is not that there are not enough people who believe in forest-reform, but that they are not sufficiently united, or, to speak plainly, that only a very few of them belong to forestry associations. That union is strength, and disunion weakness, no American needs to be told. It cannot be claimed that the forest-reformers have hitherto shown any of the fruits of strength, and that they are not united the small membership of the American Forestry Association and the few state and county societies clearly proves. The Pennsylvania Association, founded in 1886, heads the list with 650 members; but can one imagine that there are but 650 people out of the 4,000,000 inhabitants of that state who care for forest-reform, and can afford a dollar a year toward obtaining it? The smaller numbers of the American Forestry Association may be due to its origin as primarily a congress of delegates from state societies, not an association of individuals, but, owing to the lack of delegating bodies, its strength is chiefly derived from its own members. If the associations, the only visible bonds of union between believers in forest-reform all over the country, are few and small, is it not due to this that, in spite of the warnings both of intelligent men, and of drought, and flood, and land-slide, warnings whose truth is widely realized, forest destruction continues unchecked in America?

Forestry associations, especially if able (as none of them yet are, I believe) to employ paid officers or agents, can do a far greater work than the aggregate of their members individually. They can collect and diffuse information, instruct, encourage, develop public opinion, secure and enforce legislation, and work in many ways for which individuals lack time, money, opportunity or popular support. Owing to lack of means their work hitherto has been small, but not wholly profitless, and not a tenth of it would have been done without them. Besides, they give individual effort a scope and stimulus as nothing else does. A man deeply interested in forestry

is far more likely to speak and write about it, to get up meetings for it, to seek to have it taught, to urge legislation for it, to have it tried on his own land or that of his hunting and fishing-club, if he belong to an association, and feel it a duty to his associates to spread the gospel in every way he can, than if he do not; and those who can do the least individually can, by their subscriptions, greatly increase the opportunities and effectiveness of the workers.

Two very useful classes of people have as yet held aloof in large numbers from the forestry associations—viz., those who know something about forestry and those who do not. The latter, as the majority in the community, must largely constitute any forestry association which hopes to wield the powerful influence of numbers in this democratic land. They are ten times as likely to learn something about forestry inside an association as out of it, and their sinews of war are as good as those of the greatest scientists. To scientists, however, a successful association must always look for inspiration and guidance. The principal officers ought certainly to be men of reputation, especially in forestry and botanical science. How else can a forestry association attract outsiders, and show them that it exists for real work, to be done by real workers, and not to amuse a few amateurs? What influence upon public opinion and public men can an association exert when many of those best fitted for its peculiar work stand aloof? It should not be forgotten that the American Forestry Association is the child of Hough and Warder, and their successors in the work of investigation and instruction should succeed them also as the natural guardians of this and kindred bodies. Of course, every such society includes some scientific men, but not enough of them. If they think these associations too amateurish, let them personally add the leaven of practical science.

It may be urged that existing agricultural and horticultural societies can do the work. If they are willing to undertake it, well and good; but they usually exist chiefly for the instruction of their own members, whereas forest-reform, for many years to come, can only be achieved by enlightening the people and developing public opinion.

To conclude, I do not see how real forest-reform can ever be secured in this country except by the work of associations organized for that purpose. The effectiveness of this work must depend on the numbers, the liberality and the intelligence of the members. On all men and women who believe in forest-reform such a society has a claim, whether they can give but a little money and a good word, or the talents and the knowledge which have been entrusted to their keeping, not alone for their own profit and fame, but for the benefit of their fellow-men.

A Gardener's Problem.

To the Editor of GARDEN AND FOREST:

Sir.—On page 42 of your issue for January 22d, your correspondent, Mr. William Watson, illustrates his views by some statements which seem to need correction. He mentions *Nepenthes Rajah*, a plant introduced alive to Chelsea by Mr. Peter Veitch and myself in 1878—that is, about twelve years ago, instead of six years, as stated by Mr. Watson, who may, however, have been misled by the date when the plants were distributed. This inaccuracy is a trifling matter; but one of more consequence occurs in the foot-note, where it is stated that *N. villosa* thrives "only in the hottest and moistest stove," when the fact is that this plant has never yet been brought alive to European gardens. No doubt Mr. Watson, when writing, had *N. Veitchii* in his mind, a plant totally different and distinct from *N. villosa*, although formerly grown in error of its true name as *N. villosa* in English gardens.

My friend Mr. Moore, of Glasnevin, was better informed as to the native climate and surroundings of these Pitcher plants than Mr. Watson has inferred. When I presented the plant of *Nepenthes Rajah* to Mr. Moore I also told him of the native conditions, and it is a proof of his intelligence and skill that he has so far cultivated this plant when scores of other good plant-growers have failed. These native climatic conditions are so peculiar that I may here state them in a brief way. The four most interesting *Nepenthes* found wild on Kina Balu are *N. Lowii*, *N. Edwardsiana*, *N. Rajah* and *N. villosa (vera)*. They are found on the southern spur in the order named, commencing with *N. Lowii*, at 5,000 feet, and ending with *N. Rajah* and *N. villosa*, at 9,000 to 10,000 feet. This enormous mountain range is about sixty miles from the sea-coast, and the interven-

ing country consists of low ranges of coast-hills and rich alluvial plains and marshes. The topmost peak above the great southern spur is 13,700 feet high. It naturally follows that this mountain affords an enormous range of climate and temperature. The thermometer descends to freezing point at the top, and there is sleet, but no snow has been seen. The day temperature of the sea-coast and plains is generally from eighty to ninety degrees in the shade, and perhaps ten degrees lower only on the coldest nights. The great granite peaks of this mountain, even at the distance stated, are cold enough and massive enough to attract a current of hot, moisture-laden air from the sea, and this current sets in every day about four or five o'clock. The diagram here given will illustrate what occurs better than words.

Diagram showing hot and cold air currents on the sides of the mountain in Borneo, meeting and condensing at the *Nepenthes* zone.

Every night in the year there is a deluge of rain in what I have called the *Nepenthes* zone of this mountain, that is, from 5,000 to 10,000 feet in altitude, and even if not raining in the day-time there is a constant state of what has been called "Scotch mist," or air-clouds condensing into small rain, which wets one to the skin most thoroughly in half an hour. All the time I was up this mountain (I was there on two occasions in what below were the wet and dry seasons), I never had a dry thread to my back except at night in the cave with a great bonfire blazing outside. The native guides from the last village on the road, Kiau (altitude 3,000 feet), found the wet and cold (forty-nine to fifty-five degrees Fahrenheit) on this mountain too much for them, and they became quite paralyzed and finally left for their homes rather than endure the chilly dampness of this Pitcher-plant paradise. At 9,000 to 10,000 feet altitude the trees are low and scrubby, and covered with long moss, filmy ferns (here I saw the trees draped with the rare *Trichomanes pluma*, only seen alive previously by the veteran plant hunter, Tom Lobb), and Lichens or Usnea, and creeping, monkey fashion, amongst this vegetation, was only another name for a perpetual shower-bath from the branches overhead.

From what I have said, I think that my friend Mr. Watson will perceive that when Mr. Moore transferred *Nepenthes Rajah* from a hot and dry temperature to a comparatively cool and moist one, he approached the natural conditions under which this noble plant was found growing by me, and hence, no doubt, his superior measure of success. All these upland or mountain *Nepenthes* are more or less difficult of culture, and extremely difficult to import, owing to the heat of the plains and the sea voyage. On the other hand, the species found in marshy forests at or near sea level are comparatively easy, requiring heat and moisture only, with a moderate amount of shade. One *Nepenthes*, viz., the well known *N. Rafflesiana*, is the first weed to appear after forest or jungle fires in Borneo and Labuan.

Botanical Gardens, Trinity College, Dublin.

The Waverly Oaks.

To the Editor of GARDEN AND FOREST:

Sir.—Your recent editorial on the Waverly Oaks, with its plea for the preservation of the charming scene in which they stand, prompts me to lay before you an imperfect outline of a scheme by which not the scene at Waverly only, but others of the finest bits of natural scenery near Boston, might perhaps be saved to delight many future generations.

But first a few words on another pressing problem. It is everywhere agreed that a great and growing population, such as now inhabits Boston and her wide-spreading suburbs,

should, for its own best health, provide itself with all possible open spaces in the form of public squares and play-grounds. Boston (including now the various municipalities which surround her) is far behindhand in this matter. Large areas outside of the old city are wholly unprovided with public open spaces; and while the various municipalities which compose this larger Boston continue to be fearful of spending money for the enjoyment of their neighbors, there can be little hope for much improvement. The difficulty arising from the conflicting interests and desires of these many towns and cities delayed the construction of a proper sewerage system for the suburbs, until the danger and the scandal which the lack of such a system caused fairly compelled the state to create a Metropolitan Drainage Commission, with power to plan and to build a complete main drainage and to assess the cost thereof upon the towns and cities benefited. It looks now as if the acquisition of a suitable number of well distributed open spaces must wait for the appointment of a similar commission. Meanwhile the available open ground is being rapidly occupied; and Boston, like New York, may yet be compelled to tear down whole blocks of buildings to provide herself with the needed oases of light and air.

But a crowded population thirsts, occasionally at least, for the sight of something very different from the public garden, square or ball-field. The railroads and the new electric street railways, which radiate from the Hub, carry many thousands every pleasant Sunday through the suburbs to the real country; and hundreds out of these thousands make the journey for the sake of the refreshment which an occasional hour or two spent in the country brings to them. Within ten miles of the State House there still remain several bits of scenery which possess uncommon beauty and more than usual refreshing power. Moreover, each of these scenes is, in its way, characteristic of the primitive wilderness of New England, of which, indeed, they are surviving fragments. At Waverly is a steep moraine set with a group of mighty Oaks. At the Upper Falls of Charles River the stream flows darkly between rocky and broken banks from which hang ranks upon ranks of graceful Hemlocks. These two remarkable scenes have been described in GARDEN AND FOREST; and I shall name no others, though several are well known to all lovers of nature near Boston. One is the solemn interior of a wood of tall White Pines—the tree the forefathers blazoned on their flag. Another is a Pine grove on a group of knolls in the bend of a small river, where it first meets the tide and the salt marshes. Still another is a hill-side strewn with great boulders, and commanding, by a bowl-shaped hollow of the hills, a distant view of the ocean and its far horizon. At present all these beautiful scenes, excepting such as are included in the Franklin Park and the adjacent Arnold Arboretum, are in private hands; and many of them are in daily danger of utter destruction—some of the finest spots have been destroyed within the ten last years. Most of them lie outside the municipality of Boston proper. They are scattered in different townships or along the borderlines, and only an authority which can disregard township limits can properly select and establish the needed reservations.

The end to be held in view in securing reservations of this class is wholly different from that which should guide the State Commission already suggested, and the writer believes this different end might better be attained by an incorporated association, composed of citizens of all the Boston towns, and empowered by the state to hold small and well distributed parcels of land free of taxes, just as the public library holds books and the art museum pictures—for the use and enjoyment of the public. If an association of this sort were once established, generous men and women would be ready to buy and give into its keeping some of these fine and strongly characterized works of nature; just as others buy and give to a museum fine works of art. Indeed, the association might even become embarrassed, as so many museums are, by offerings which might not commend themselves to its directors.

Lovely natural scenery supplies an education in the love of beauty, and a means of human enjoyment at least as valuable as that afforded by pictures and casts; and if, as we are taught, feeling for artistic beauty has its roots in feeling for natural beauty, opportunities of beholding natural beauty will certainly be needed and prized by the successive generations which are to throng the area within ten miles of the State House. As Boston's lovers of art united to found the Art Museum, so her lovers of nature should now rally to preserve for themselves and all the people as many as possible of these scenes of natural beauty which, by great good fortune, still exist near their doors.

Boston.

Charles Eliot.

Orchids in Brooklyn.

To the Editor of GARDEN AND FOREST:

Sir.—It would be difficult to find better specimens of *Phalænopsis* than those in the collection of Mr. Frederick Scholes, of Brooklyn, and at this season of the year, when great numbers of them are in bloom, they are specially attractive. There were more than 2,000 fully expanded flowers on February 20th and the spectacle was one not easily forgotten. Among the plants I noted some good examples of *P. Schilleriana*, literally covered with its beautiful mauve colored blossoms, one specimen having eight spikes, which were short, well branched and carried over 300 flowers. To this variety the owner has given the appropriate name of *P. Schilleriana compacta*. It has three strong growths, and eighteen broad, leathery leaves, which measure from ten to fourteen inches in length. Another specimen of an admirable variety was carrying 200 flowers, while a dozen others were also equally well flowered. A fine specimen was a plant of *P. grandiflora*, with three growths and thirteen leaves, which had three strong spikes, well covered with large white blossoms. *P. amabilis* was well represented by specimens with strong stems freely branched and covered with flowers. One plant with eight very large leaves had a spike three feet long. The white and purple-spotted flowers of *P. Stuartiana* were very attractive, and one plant had produced a panicle carrying sixty flowers. *P. Sanderiana*, which much resembles a rose colored *P. amabilis*, was represented by several very dark varieties. The plants occupy wire baskets, and are suspended some two feet from the glass, and are grown moderately warm. On the stages few Orchids were seen, the space being occupied by Palms, Ferns, Eucharis, etc., which are syringed daily, furnishing an atmosphere which the plants above appear to thoroughly enjoy. In the same structure several plants of *Cattleya Lawrenceana* were in bloom, as well as of *C. intermedia*, *C. speciosissima* and *Dendrobium Ainsworthii*. Several plants of the scarce *Odontoglossum Humeanum* were in the house set apart for cool Orchids, together with the pretty yellow and brown spotted *Oncidium micropogon*, and the orange-scarlet flowered *Lalia harpophylla*.

A. Dimmock.

Summit, N. J.

Periodical Literature.

The most interesting paper in the December number of the *Kew Bulletin of Miscellaneous Information* for horticultural readers is an account of the tropical and sub-tropical plants growing in the gardens of the Riviera, from the pen of our London correspondent, Mr. W. Watson, who was sent last autumn by the authorities at Kew to examine the garden vegetation in southern France, for the purpose, primarily, of determining whether many plants now grown in England, in stoves and other warm houses, might not be treated more successfully in a more temperate atmosphere. Mr. Watson's report contains most valuable information for the gardeners of southern California, where the climate is not unlike that of Provence and of the southern Atlantic states, and nothing but its length prevents us from reproducing it entirely. Our quotations, however, must be confined largely to Mr. Watson's remarks about Bamboos, plants which American gardeners know very little about yet, but which are beginning to attract considerable attention both in California and in Florida and Georgia. "After the Palms," he says, "the most tropical feature in the gardening of the Riviera is the Bamboos, which are largely used in the composition of the best gardens, both public and private. To a northern gardener the elegance and grandeur of some of these Bamboos constitute some of the chief charms of the Riviera. Some of the specimens are very large, as for instance one of *B. vulgaris*, in Baron Vigier's garden at Nice, which measures forty feet through in every direction, and is thirty-five feet high. It contains hundreds of stems or canes, each three inches in diameter, and straight and smooth as a gun-barrel. It is planted on one side of the lawn near the house. As fences, screens and boundary lines the Bamboos are frequently used, and nothing could be better, as they are quick growers and evergreen. All the kinds noted were in splendid health, and from the manner in which they had taken possession of the ground, it was evident that their requirements are abundantly satisfied. The finest and healthiest examples are in wet ground, often on the edge of water. Most of them are heavily manured annually.

"In England we have not hitherto made the most of this beautiful family of plants, many of which may be grown out-of-doors successfully in all the milder parts of the country,

whilst in large conservatories, where they would get protection from cold in winter, a still greater number would be found to thrive. That they are much superior to many of the plants at present used for such positions must be evident to any one acquainted with the extraordinary elegance and grace of a well-grown Bamboo.

"The Kew collection comprises over fifty named sorts, a few of which are tropical, whilst the bulk of them are either quite hardy or require only the temperate conditions supplied by the winter-garden.

"The names of Bamboos are as confusing as are those of garden Palms. In one as in the other it is only very rarely that the plants flower under cultivation, so that many of the names, which are given by nurserymen, can only be problematical. For garden purposes this would not be of much consequence, the difficulty arising only when growers do not agree as to what names the plants shall bear.

"Now that so many kinds of Bamboos are in cultivation under favored conditions on the Riviera, it would be worth while to watch them, and as they flower, get them properly determined.

"It is generally supposed that nearly every member of the Bamboo order perishes immediately after flowering. There are many recorded instances of this having occurred. But with regard to a considerable number of the species the exact flowering age has not been ascertained. Some are said to grow forty years before flowering. Another remarkable fact is that all the plants of one generation flower at the same time, no matter how different may be the conditions in which they happen to be placed. I was told that all the plants of *Thamnocalamus Falconeri* (*Bambusa gracilis*) of the Riviera flowered and died last year. Numerous seedlings have since sprung up about the old stools, but the latter certainly all perished. This proved to be the case with a plant of *Arundinaria falcata*, which flowered at Kew in 1886.

"The following are the kinds noted. The names in brackets are what I consider to be the correct names, according to Munro, etc.

"*B. aurea*.—A Japanese species, now well known in gardens. It was in cultivation at Kew in 1866, and is here still. It is one of the most elegant of the hardy Bamboos. In the gardens of the Acclimatization Society, at Hyères, there is a magnificent specimen with stems twenty-five feet high, and not more than one and a half inches in diameter. The nodes are prominent, and less than four inches apart on the lower part of the stem. When ripe the stems are of a rich greenish yellow color. The leaves are small, with a distinct petiole.

"*B. gigantea* (*Dendrocalamus giganteus*).—The largest of all the Bamboos. The specimen in the Palm House, at Kew, produces stems forty feet long and twelve inches in circumference, but wild plants have stems as much as twenty-six inches round. In the garden at Villa Valetta, Cannes, there is a very fine mass, with stems thirty feet high and four inches in diameter. It is a native of India.

"*B. gracilis* (*Thamnocalamus Falconeri*).—A slender and somewhat fragile stemmed plant from the Himalayas. It is not uncommon in gardens, as it makes an elegant pot plant. It was plentiful on the Riviera till last year, when all the plants flowered. There is a plant at Hyères called *B. gracilis rustica*, in which the leaves are narrow, with incurved margins.

"*B. Mazellii*, Hort.—Fine masses at Hyères and at Cannes. The stems are twenty-five feet high, bright yellow when mature, the nodes prominent and close together at the base, the branches loose, and the leaves short and twisted on the petiole. It looked suspiciously like *B. aurea*.

"*B. Metake* (*Arundinaria Japonica*).—Much used on the Riviera, where it is as ornamental as it usually is in England. It is always strongest when grown near water, although it grows well in an ordinary border. At Kew there is a specimen twelve feet high. According to Munro it is known as *B. mitis* in the gardens of Paris.

"*B. mitis*.—A magnificent specimen on the lawn at Villa Valetta, the stems thirty feet high and three inches in diameter at the base, becoming shining yellow with age. The nodes are prominent and about nine inches apart, the leaves short and not dense. There is a small plant of it at Kew, obtained last year from Lavallée's collection. It is said to be from Cochin China.

"*B. (Phyllostachys) nigra*.—A clump of this, twenty yards through and rising to a height of thirty feet, in the garden of Baron Vigier at Nice, was one of the most striking objects seen on the Riviera, thousands of naked, shining, blackish purple stems rising from the lawn and losing themselves in the mass of green foliage above. This species is quite

hardy in England, but it does not grow to its full height except when in a very sheltered situation or under glass, as at Chatsworth, where in the large conservatory it is exceedingly handsome.

"*B. quadrangularis*, a very interesting species from China, with stems fifteen feet high by one inch in diameter, and distinctly quadrangular; the nodes are armed with decurved teeth-like spines. These dimensions are of a clump six feet through on one of the lawns at Villa Valetta. There are plants at Kew, both outside and in the temperate house. It is a handsome and distinct Bamboo. For an account of it see an article in *Nature*, vol. xxxii. (1885), p. 391.

"*B. Quilloyi*.—I cannot find any information with regard to this plant. Carrière described a Bamboo in the *Revue Horticole*, under the name of *B. Duguiltoii*, but Munro appears to have referred this to *Phyllostachys puberula*, included by him under *P. nigra*. The plant known under the above name is represented at Hyères by a large clump with stems twenty-five feet high, one and a half inches in diameter, bright yellow, with a faint tendency to become quadrangular. We have a plant of it at Kew. It is a most elegant Bamboo.

"*B. scriptoria*, Hort. (*B. nana*).—I believe that *B. scriptoria* of the Riviera gardens is merely a form of the well known Chinese *B. nana*. It has the same dense habit, thin green canes, and small leaves with the under side glaucous, which characterize *B. nana*. In some of the specimens seen the stems were nine feet high. A variegated form called *B. scriptiorionis* is the same as is grown at Kew as *B. nana variegata*.

"*B. Simoni*, a beautiful Bamboo, and perfectly hardy in England, as is shown by the fine example in the Cambridge Botanic Garden, and by the plants at Kew. It is also very handsome at Hyères, where the canes are fifteen feet high, quite smooth and cylindrical, less than an inch in diameter and colored deep olive green. This plant is worth the attention of English horticulturists on account of its elegance and hardiness, and its evergreen character.

"*B. sulphurea*.—Apparently a garden name for a very handsome Bamboo, with stems eighteen feet high, one and a half inches in diameter, the nodes nine inches apart, and the internodes deeply furrowed on one side. When mature the stems are rich orange-yellow in color. There is a fine mass of it at Villa Valetta. It is also in the Kew collection.

"*B. verticillata*.—This is probably the 'Male Bamboo' (*Dendrocalamus strictus*), a common Indian species, the stems of which, according to Munro, are universally used as lance-staves. The specimens seen were large clumps, the stems twenty feet high, one inch in diameter, the nodes at the base a foot apart, the upper ones bearing each a crowded cluster of short leafy branches. When old, the stem is bright yellow. It is a well marked, handsome Bamboo.

"*B. virescens*.—A beautiful Chinese Bamboo which was introduced to the Jardin d'Acclimatation in 1870, in the branch of which at Hyères a fine clump was noted. The stems are ten feet high, three-fourths of an inch in diameter, much branched toward the top, the internodes somewhat flattened on one side, and striped with violet on a greenish yellow ground. The leaves are glaucous on the under side. Young plants of it are in the Kew collection.

"*B. viridi-glaucescens*, Hort.—One of the handsomest of cultivated Bamboos. It is quite hardy in England, and in France it is one of the commonest. It grows very rapidly, has handsome foliage, transplants easily, and is a first-rate pot plant. It is frequently used in France for the embellishment of entrance halls, and is very effective. The stems of the Riviera plants were over twenty feet high, very slender, the nodes about a foot apart, dark green when young, bright yellow when mature.

"*B. vulgaris* (*B. Thoursii*).—Some astonishingly large, healthy specimens of this well known species were met with. Apparently it does not require tropical treatment such as it usually gets. At Hyères, Cannes and Nice it is especially fine, in the last named place measuring forty feet through and the canes thirty-five feet high. The plant in the Palm house at Kew must be thirty years old; it has not yet flowered."

Palms are the most prominent feature in many of the towns of the Riviera, and the chief beauty of many gardens is produced by groups or single specimens of Palms of various kinds. At Hyères the common Date Palm is used as a street tree, and at Bordighera this Palm is extensively cultivated for the sake of its leaves, which are used for the decoration of churches and are sent as far away as to Paris. No less than sixteen genera of Palms are represented in these gardens. Mr. Watson describes the Washingtonia, the Desert Palm of California, as "one of the glories of the Riviera," and

reference to this plant is made again in his letter on page 112 of this issue.

Next to the Washingtonia, *Phoenix Canariensis* seems to be the most satisfactory Palm in the gardens of the Riviera, where it grows very rapidly and soon forms a magnificent head. Agaves, Furcraas, Beaucarneas, and other so-called succulent plants flourish in these gardens, where Yuccas are seen in greater variety and beauty probably than anywhere else. There is a specimen of *Yucca filifera* (see GARDEN AND FOREST, i. 78.) in the gardens of the Villa Valetta with a stem three feet in diameter at the base, and several other species or varieties are represented by large individuals.

Notes.

Théodore Frœbel, the founder and head of the well known nursery establishment of Frœbel & Cie., of Zurich, retires from active business, and is succeeded by his son and partner, Otto Frœbel, in whose name the business will now be conducted.

Aralia Sieboldii variegata is attracting attention as a handsome and serviceable plant for house decoration, its tough leaves being well adapted to such use. The variegation appears, however, to be somewhat fickle, and possibly may be much improved by proper selection.

Experiments in Olive culture, made by the University of California, are of great value to all growers in that region. Twelve imported varieties have been grown at the agricultural stations, and the result shows that between the Mission and Picholine, varieties mostly grown in California, the Mission is far superior in amount of meat and yield of oil.

The hybrid perpetual Rose, Ulrich Brunner, has been forced quite early in the season in a number of the large Rose establishments, and has proved the finest bright red Rose for this purpose. It is of large size and particularly lively in color. As an offset to this, however, it is claimed by some growers that this Rose is hardly productive enough to become a very profitable variety for forcing.

Another reminder of the prevailing mildness of the present season was seen at the recent meeting of the Pennsylvania Horticultural Society in the form of flowers of the Cape Pond Weed (*Aponogeton distachyon*) from out-doors. The exhibit in which this was seen was from the garden of a lady living near Philadelphia, and included cut blooms of about a dozen other species of flowering plants, most of which looked strangely out of season in February.

Dr. Harris states that the seeds of imported Watermelons do not change in form, size or color by being grown here, as those of the Cantaloupe do, except under hybridization. The number that is produced by one fruit is occasionally very large, as high as 1,160 perfect seeds, of a weight of five ounces, having been taken from a melon of forty-nine pounds. Such productiveness is rare, as the number rarely exceeds 600; that of the Calabash reaching the same, the Cantaloupe 500 or more, and the Cucumber 450.

At the February meeting of the Pennsylvania Horticultural Society, held in Philadelphia, an attempt was made to test the relative popularity of the hybrid perpetual Roses, Madame Gabriel Luizet and Mrs. John Laing; the choice was made by ballot, and resulted in a majority of twenty-seven votes in favor of Madame Gabriel Luizet in a total vote of about ninety. A similar contest between La France and the Duchess of Albany resulted in a majority for the first-named. It would seem that these two varieties (Madame Gabriel Luizet and La France) are securely fixed in the affections of the Philadelphia horticulturists, and may not easily be displaced by the newer varieties, even though these are Roses of the very first rank.

Orange culture at Jaffa, according to Consul Gilman, has become an industry of great value. Of the 9,000 acres of cultivable land pertaining to the community, 3,000 acres are covered by Orange groves and gardens; and these are all under irrigation. Among the other fruits produced are the lemon, lime, citron, date, peach, apricot, grape, fig, pomegranate, plum and melon, as well as the olive. All the ordinary garden vegetables are also grown here of good quality and in abundance. Of late, the Vine, especially, is receiving increased attention and care; extensive vineyards are being planted; and as here the Vine is free from the diseases and insect pests of other countries, and the soil and climate are peculiarly adapted to it, this should be one of the most flourishing wine-producing countries in the world. The Olive does best in the hill country, and generously responds with abundant crops to the slightest care.

Dr. C. C. Parry died at his home in Davenport, Iowa, on the 20th of last month, from pneumonia, which followed an attack of influenza, contracted in the east. He paid a long visit to botanical friends in the autumn and early winter, and while here was busy investigating various matters connected with the California flora. He was then in perfect health apparently, active and alert in mind and body, and full of plans for new work. He was enthusiastic in discussing new expeditions in the far west, and full of reminiscences of travel and adventure. Though sixty-six years of age, we little thought then that our friend's wanderings were so near an end.

Charles C. Parry was born in Admington, England, on August 28th, 1823. His family emigrated to America nine years later, and settled on a farm in Washington County, New York. Dr. Parry was educated at Union College, and then studied medicine. He was interested, however, in botany even at this period of his life, and although he practiced his profession for a short time in Davenport, where his family removed in 1846, he soon abandoned it for the more congenial pursuit of natural history. He had devoted much attention to collecting the plants of New York before he moved to Iowa, and these studies secured for him the acquaintance of Dr. John Torrey and Dr. Asa Gray. Their acquaintance confirmed his taste for botanical exploration and exerted a powerful influence upon the remainder of his life.

Dr. Parry's real work as an explorer began in 1849, when he was attached to David Dale Owen's survey of Wisconsin, and made a collection of plants in the valleys of the St. Croix and St. Peter Rivers. The next year he joined the botanical staff of the Mexican Boundary Survey, and crossed the California desert from San Diego to the mouth of the Gila River. This journey and the subsequent ones which he made as a member of the survey, and which extended through two or three years and carried him overland from the Pacific Ocean to the Gulf of Mexico, were rich in botanical discoveries of the most interesting character. These are found recorded in the "Report of the Mexican Boundary Survey," published in 1852. Persons who cross these deserts now in Pullman palace cars can form a very slight idea of the sufferings and hardships of these early explorers, who passed months in traveling distances now covered in as many days.

Dr. Parry's next conspicuous service to American botany was performed in 1861, when he began his examination of the flora of the central Rocky Mountains. This work, undertaken mainly at his own expense, occupied him several years. The Colorado mountains were at that time a fresh field, practically, their flora being known only by the scant material brought back many years before by the naturalist of Major Long's expedition, and Dr. Parry was able to reap a rich harvest from the plants which extend to the summits of the alpine peaks, which he was the first botanist to reach. He made, too, at this time, valuable meteorological and topographical observations, afterward elaborated by Dr. Engelmann. Dr. Parry was appointed in 1869 as Botanist of the Agricultural Department at Washington, and occupied this position for two years. He was, however, an explorer by temperament and by habit, and he had little liking for the restraints of an office position. This taste for travel he was able to gratify for the last twenty years, during which he was more or less continuously in the field, either in Nevada and Utah, where he made many discoveries, or in Mexico and California, where much of the last part of his life was passed. He always kept his home, however, at Davenport, in whose Academy of Natural Sciences he was deeply interested. This he made, several years ago, the depository of his herbarium, which was, of course, exceedingly rich in western plants, and which, besides his own collections, contained those of many correspondents.

Dr. Parry discovered hundreds of new plants afterward described by Dr. Gray and by Dr. Engelmann, and his name is so firmly fixed in this way in the history of American botany that, although he published very little, it will be remembered as long as the plants of western America continue to interest the students of botany. Horticulturists will not forget that it was Dr. Parry who discovered *Picea pungens*, the beautiful Blue Spruce of our gardens; *Pinus Engelmanni*, *Pinus Torreyana*, *Pinus Parryana* and *Pinus aristata*; nor that it was through his zeal and enterprise that many plants now familiar to us were first cultivated. With Dr. Parry there passes away the last, with a single exception, of the remarkable group of men who became prominent as botanical explorers soon after the great addition to the territory of the United States which followed the close of the Mexican War, and who, fired by the enthusiasm of Asa Gray, opened to the world under his guidance the botanical treasures of the western and south-western parts of this country.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MARCH 12, 1890.

TABLE OF CONTENTS.

Legislation for the Adirondacks.

THERE are several bills relating to the Adirondacks now before the Legislature at Albany, which propose radical changes in the character of the forest reserve and its administration. The recommendation of the Governor that a Commission of five men be empowered to fix the boundaries of a "state park" consisting of from 2,500 to 5,000 square miles, seems to meet with little favor, and a bill presented by the Speaker of the House, and embodying in the main the Governor's plan, has been practically withdrawn. Another bill, authorizing the establishment of such a reservation under the direction of certain citizens named in the bill, has been presented in the Assembly, but it will probably fail.

At this time it seems probable that Senator Sloan's report on the Governor's plan, which has already passed the Senate, will be concurred in by the House. This resolution empowers the present Adirondack Commission to consider the project of a so-called park to include the lands about the head-waters of the main streams which take their rise in the wilderness, and report on its size, location and probable cost. It is evident that there is no salvation for the woods unless the state acquires absolute title to them, and preparation for such purchase should be made without delay, but it should be remembered that ownership by the state in fee simple is not of itself a guarantee that the wilderness will be safe. One of the proposed park bills, for example, contemplates the leasing of its lands by the state in lots of twenty-five acres, and this provision would mean absolute ruin to the forest.

No legislation will be satisfactory unless it is based on the principle that the first and only sufficient reason why the state should hold a great tract of land within its borders is that it is essential that this particular region should remain forest-covered always so that the flow of the great water-ways of the state need not be impaired. The ruin of the Adirondack forests means the ruin of our rivers, and it is impossible to secure the preservation of the forests

for all time unless they are controlled by the state working under a permanent policy. All other questions regarding the North Woods are unimportant in comparison with that relating to the water supply. It is very well to have a sanitarium, and it is proper that people should be able to enjoy the refreshing contact with wild nature; but, after all, these are secondary considerations.

Again, if the forest is to remain and reproduce itself for all time, the fewer people who live within its borders, besides its custodians, the better. If the state acquires a large area it will be necessary, of course, to establish, at convenient points, public houses for the protection and entertainment of visitors. But this is a different thing from leasing the state land to individuals. If one man is entitled to a good site on a lake-shore for a fancy camp or a summer villa, the privilege cannot be denied to his neighbor without injustice. No matter how wild and picturesque these people intend their summer homes to be. Each one clears a little and burns a little more, and the forest, as a forest, is doomed. It is only necessary to examine the neighborhood of Paul Smith's to learn what settlement in the forest can accomplish in a very short time.

The two immediate dangers which threaten the North Woods are (1) the extension of railroads into the wilderness, for a railroad through a forest means its extermination; and (2) the legalized use of the woods as the summer homes of wealthy men. Any enactment which does not recognize and guard against these dangers will fail to accomplish its highest purpose.

The hard pine of the south, although the supply has generally been regarded as practically inexhaustible, as the supply of white pine was considered inexhaustible a few years ago, seems to be in danger of exhaustion much more rapidly than was supposed possible ten years ago. The demand for lumber of this description is increasing all over the world, and more and more of our hard pine is sent every year to Europe, South America and Australia, while the home consumption is doubling every few years. The saw-mills of the Southern Pine-belt are now kept running to their utmost capacity, and new mills are projected in all directions. The amount of this lumber exported last year from the United States exceeded the amount exported during the previous year by about forty per cent., while Great Britain took an excess of more than fifty per cent. over her importations of the previous year. It is believed that the output of the hard pine mills will be this year much greater than it was last, and that prices are to be considerably higher.

There is still a very large amount of this timber left standing in the Pine forests which extend along the coast from North Carolina to Texas; and there are still regions in which the sound of the axe is still practically unknown. The southern pine forests, however, are encroached on more seriously every year by the manufacturers of turpentine, who destroy a vast amount of timber with very little profit to themselves. But the real danger in the situation is that these forests of Pine are nowheres reproducing themselves. It is the custom, dating from before the time of the coming of Europeans to America, to burn over every spring the whole territory covered by these forests for the purpose of improving the scanty pasturage which is found among the trees, and this burning, renewed year after year, has destroyed all seedling trees, and so changed and deteriorated the character of the soil that it cannot produce again timber of commercial value. The situation is briefly this: The consumption of hard pine is increasing in a remarkable and unexampled manner. Reproduction is at a standstill. It can only be a matter of time, therefore, when the commercial importance of the Pine-forests of the south, which once contained, and perhaps still contain, the greatest body of accessible building timber of the very highest class the human race has ever seen, will be a thing of the past. No

other Pine forests produce such valuable material, and it is not very evident where the world is to find a substitute for our southern hard pine.

The number of books which have been written on the art of landscape-gardening since the arrangement of gardens and of pleasure-grounds was elevated by the poets of the seventeenth and eighteenth centuries to the rank of a fine art appears surprisingly small, when the attention to everything relating to country life, especially in England during the last two hundred years, is remembered. It is not less surprising that this literature is so generally overlooked, and so little known by the very persons who would be expected to be most interested in it, and that no serious effort has yet been made by any of the great libraries to form a complete collection of books relating to the history and arrangement of gardens. There is, however, a re-awakening of interest in the landscape-gardening art, especially in this country, where there is now every indication that its principles are to be more generally applied than they have ever been before, not only in the construction of the parks and pleasure-grounds which are springing into existence in the neighborhood of all the great centres of population in the United States, but in the more prosaic, but not less useful, arrangement of towns and villages, to which the trained landscape-gardener can bring the health, convenience and beauty which will add so much to the material welfare and development of the American people. As the knowledge of the art increases and the importance of its relations to a civilized people comes to be more generally understood, the interest in this literature, which contains a few works of cardinal value, and several of great mechanical beauty, will increase. It is desirable, therefore, that as complete collections of these books as it is possible to secure should be found on the shelves of our principal libraries, that those who practice the art, and those who study its principles, may have it within their power to learn all that books can teach them on the subject. With this view in mind, and for the purpose of aiding librarians in a search for books relating to the garden, we have obtained the permission of a correspondent to print the list of publications which have appeared on the art of landscape-gardening since Bacon first defined its scope and aims. The list has been prepared under exceptionally favorable circumstances, and is much fuller and more complete than any bibliography of the subject which has appeared. That it is not complete, however, there is probably little doubt, and corrections and extensions are asked for, in the interest of fuller information upon a subject of much literary and artistic importance.

Some Old American Country-Seats.—IV.

CLERMONT.

NEW ENGLAND, in the old days before the growing up of the great cities, possessed many towns in and near which dwelt people of polite cultivation and polished manners, whose sober, but often stately, mansions yet remain. In the seaboard towns especially, such as Portsmouth, Newburyport, Salem and New Bedford, still stand numerous examples of this appropriate urban architecture, substantial buildings, with light and some space about them, and sometimes a court-yard enclosed by a high wall in the English fashion. At Kittery, at New Bedford and elsewhere, not to speak of numerous, but fast disappearing, examples near Boston, mansions of this character may be seen standing well out of town in small parks of their own. It should be noted that the three old Bostonian country-seats, already described in this series of brief papers, have been chosen only because of their exhibiting more than usual breadth of landscape-setting, combined with more than usual excellence of general design.

Passing now from New England to New York, from the region of small hills and ponds and streams which surrounds Boston to the prospect-commanding banks of the broad Hudson, and again selecting ancient country-seats which excel in point of design, we come first to Montgomery Place, at Barrytown.

Barrytown is itself but a very small village, about ninety

miles from New York and some fifty from Albany, and it is so surprising to find here an old seat of the first class, that this number of the series must be devoted to an explanation of the fact. The Hudson River naturally attracted settlers very early. The Dutch established a trading-post at Beavercreek even before they built their fort of New Amsterdam, and here the Van Rensselaers held sway as Patroons during many years. After the English gained possession of the country, and renamed the chief towns New York and Albany, the river-lands began to be parceled out among such persons as applied for them and could persuade the Indians to sell their hunting-grounds for coats, hatchets or beads. Among others who thus obtained a manor was Robert Livingston, an immigrant of 1674, son of a clergyman who had been exiled to Holland for non-conformity. This gentleman married the widow of the Patroon, and was made lord of the manor of Livingston in 1685 by Governor Dongan, who granted him title to 150,000 acres with a frontage of about fifteen miles on the east bank of the Hudson River, opposite the Catskill Mountains. After a younger son of his, also named Robert, had distinguished himself by frustrating an Indian plot, he set off the southern part of his ample domain beside the river, and gave it to this son, making him lord of a new manor, which he named Clermont. The Clermont manor-house stands intact, its stout walls having survived the fire set by British raiders just before Burgoyne surrendered in 1777. It is approached by a long winding road, which descends from the highway through a wild woodland. Near the house the road divides to send a branch to the kitchen-door and to the stable, and the main road ends with a turn placed most unfortunately between the house and the river. The house is a square building with two low wings, and stands on a natural terrace within half a stone's throw of the low bluff which here makes the river's shore. Immediately behind it rises a bank of forest-trees, the edge of Clermont Woods, and before it, in an irregular row on the brink of the bluff, stand a dozen huge Locust-trees, doubtless the ancestors of many others which adorn the numerous Livingston properties along the river. One of these great trunks measures six yards in circumference, and shows to this day the marks of British cannon-shot.

From Clermont a short walk southward through an avenue of tall and crowded Locusts brings one to another and more elaborate mansion, situated upon the same natural terrace, backed by the same hanging woods, and commanding the same view of the river and the Catskills. This house was built by that Robert R. Livingston who was a delegate from New York to the Congress of 1776, and became first Chancellor of the State of New York, Minister to France and a patron of Robert Fulton. The ground plan of his house is in the form of an H. The central hall in the middle of the H is entered from either court; and a long corridor, which looks on the river court, and is hung with family portraits, connects the drawing-room in one wing with the dining-room in the other. The external walls of the house are white, the great rooms in the low wings have long windows opening nearly to the ground, and the two stories of the central block are crowned by an elaborate white railing. Across the ends of the wings and the river court extends a platform at which carriages may draw up, and a carriage-road makes a rectangle about the whole house. A more interesting example of domestic architecture in the formal style does not exist in America. Its owners, men who were conspicuous in the political struggles of the young Republic, were often compelled to make the long journey to New York; but they always returned to Clermont as to their one permanent home—so strong, even after manorial privileges had been abandoned, was their old English liking for country-life and country-leisure. Montgomery Place, at Barrytown, was an offshoot of these manorial seats at Clermont. Like several other old seats upon the Hudson, it would never have been created had not Governor Dongan and his superiors in England attempted to plant in America the English manorial system.

Boston, Mass.

Charles Eliot.

The California University Gardens.

ALTHOUGH the careful and constant work of Professor Hilgard and his assistants has created what is already, in important respects, a "Botanic Garden," it is modestly divided, in his reports, into the "Agricultural Grounds," the "Experimental Grounds" and the "Garden of Economic Plants." Berkeley, although exposed to the sea winds, is high above the valley, and much has been done to naturalize a great variety of plants there which are popularly supposed to thrive only in the southern counties of the state.

When the site for the University of California was to be

chosen many considerations were involved. There were valleys, east of the Coast Range, warm and well watered, that offered magnificent situations, but they were too far from San Francisco, the commercial centre. Berkeley, fronting the Golden Gate, with the Contra Costa Mountains behind it, combined the greatest number of advantages. Here, too, small but beautiful streams, flowing from deep, rocky and wooded cañons, united at the edge of the valley; here were copses of Laurel and Alder, and noble groups of Sycamore Maple and Live Oak; here was a large extent of rolling upland, sloping to the bay on the west, and rising on the east into rugged mountains. Every botanist and landscape-gardener who saw the place was charmed with its possibilities. Frederick Law Olmstead was asked to make a plan for the University grounds and the adjacent town. This plan was subsequently stolen or destroyed, and every effort to secure capable landscape-gardening was for some time frustrated. A man who had millions of *Eucalyptus globulus* seedlings managed to sell several hundred thousand of them to the University authorities, and they were planted everywhere. Instead of the garden art that every educated Californian wanted to see, Berkeley became for years a wilderness of tall, crowded Eucalypti, and all its natural beauties were obscured. A broad avenue winding about the base of the hills for miles, which had appeared in Mr. Olmstead's plan, was almost entirely lost. Even the town yielded to the prevailing Eucalyptus craze, and soon rivaled the University in its stiffness.

The great Oaks were still left below the University building and along Strawberry Creek, and, ten years later, as wiser counsels prevailed, the Eucalypti were thinned out and left for a background and for occasional masses on the hills. Part of the warmest ravine and plateau south of the main creek had been sold, unwisely, and against the advice of those who wished to see a botanic garden established. But at the north side of the University tract was a low hill-slope, with southern exposure, and a few acres of rich bottom-land along the creek below. Here propagation houses were built, and the long task of substituting valuable and beautiful plants for the foolish monotony of surplus Eucalyptus-trees was begun by the Agricultural Department.

The evil of the past is now nearly obliterated. English and other Oaks form one plantation. Some of the most beautiful Australian Acacias are grouped among the California conifers. Sheltered south of a belt of Live Oaks are Palms in great variety, and there are great masses of Bamboos. The experimental orchard and vineyard are on a hill-slope, with the economic garden south-west on the plain. Steadily, persistently, the work of covering the hundred or more acres of available land with rare and valuable plants goes on under Professor Hilgard's supervision.

My own memories of the University gardens go back to 1876, when I used to spend Saturday afternoons in the plant-houses helping a good-natured gardener, and taking my pay in seeds and cuttings of whatever happened to strike my fancy. It was an amateur sort of a place in those days, however, with very little that the florists did not have, and no system worth mentioning. The most brilliant event of that decade was to plant thousands of white and red Mesembryanthemums on the hot hill-slopes and around the University buildings, which the irreverent students presently named "Faculty Onions," and laughed to scorn, rightly preferring turf, or even Wild Oats.

By 1880, after the work of propagation had been well systematized under the direct supervision of Mr. W. G. Klee, a great many valuable trees and shrubs were distributed over California besides the specimens that found place in the grounds. Among them were five species of Cinchona—*C. Calisaya*, *C. succirubra*, *C. condaminea*, *C. officinalis* and a hybrid from India.

The winter of 1887-88 killed all the Cinchonas, although *C. officinalis* and the hybrid had withstood all former winters by means of slight protection, and were nearly ready to bloom. All the distributed trees, excepting those at Mrs. Whitney's, San Diego, also died. The regions in this state adapted to this tree are evidently limited. The warmest mesa lands of the extreme southern part of the state promise a moderate success.

The Carob (*Ceratonia Siliqua*) is quite hardy, as is also the Caper (*Capparis spinosa*). The Japan Vegetable Wax (*Rhus succedanea*), also *R. vernicifera*, are free growers and ornamental, and, with the *R. Coriaria*, perfectly adapted to California. *Anona muricata*, the Sour Sop, was a failure, and *A. Cherimola*, only suited to greenhouse culture at Berkeley, thrives in the southern parts of the state. The Tamarind-tree is very tender and a slow grower. Among other trees planted and doing well are the *Argania Sideroxylon* of north Africa, and the *Berberis heteropoda* of Turkistan.

The experiments with Oaks deserve especial attention. The eastern species, such as *Quercus nigra*, *Q. coccinea*, *Q. alba* and others, are slow growers. The English *Q. Robur* is a great success, surpassing in rapidity of growth all other sorts two or three times over. Acorns planted in 1878 are now large trees. This species of Oak is recommended by the University for planting in all parts of California. The Cork Oak has been distributed for the past two seasons, and reports indicate its adaptation to a very large area, but more especially to the foothills of the Sierra Nevada.

The growth of the Wild Cherry (*Prunus serotina*) and of the Box Elder (*Negundo aceroides*) has been all that could be desired, but the two Hickories tested, *Hicoria glabra* and *H. alba*, have been extremely slow, and will not pay to plant here. A Japanese tree, the *Zelkova Keaki*, makes a fine growth.

Since 1880 the work of the University gardens has been broadened in many directions. Carob-trees sent out are growing in Napa, Colusa, Los Angeles and other parts of the state. The largest Carob-trees in California are near Los Gatos, on the farm of Mrs. Arnerich, the widow of a Dalmatian who planted seeds in 1873 producing some twenty-five trees, now fifteen feet high, with trunks nine inches through. Trees of equal age, though not so large, are in bearing on the farm of James Shinn, Niles. The Carob seems to be perfectly at home on the California hill-sides.

The yellow Guava, *Psidium pyrifera*, only succeeds in sheltered spots in the southern counties and in the Sierra foothills. *P. Cattleianum* proves hardy at Berkeley, on the Oakland foothills, and in many places throughout the state. The Melon-tree (*Carica Papaya*) failed in most places. At last a small plant was sent to Mrs. Whitney, of National City, San Diego, and in three years it grew to a height of twelve feet, and has borne fruit every season since. The Pistachias, both *Pistachia vera* and *P. Terebinthus*, are being planted in many places. The latter grows rapidly and is hardy; the former is a slow grower, but promises well. The largest in the state are at Niles.

The Camphor, *Camphora officinalis*, is an entire success. On the Hayward estate, San Mateo, are trees forty-five feet high, with trunks three feet in diameter. The Camphor thrives here wherever a Peach or Pear will grow, and hundreds of trees are now planted on every kind of soil. It promises to become one of the great avenue trees of the future. One of the Cinnamons, the *Cinnamomum glaucum*, seems to be as hardy here as the Camphor.

Among the rare Chilean shrubs growing at the University are the handsome-leaved *Boldoa fragrans*; the *Persea lingua*, whose timber is used for cabinet work; the thorny hedge plant, Espino, and the *Psoralea glandulosa*, which is used to some extent for planting on drifting sands. The Acacia that has been most widely distributed is the *A. decurrens*, or Black Wattle, which proves of rapid and easy growth from Shasta south. *A. dealbata* and *A. melanoxylon* are equally fast growers. The only possible objection to the Acacias is that the forests are liable to become infested with the Cottony scale. Mr. Klee tells me that since the introduction of the Australian Lady-bird, which feeds on the Cottony scale, he considers all danger to the Acacias from this source over, and thinks they cannot be recommended too highly. The famous Jarrah, *Eucalyptus marginatus*, is hardy in many places about Berkeley.

Of Olives, two valuable varieties introduced by the University from Spain are the Manzanillo and the Nevadillo Blanco. They have been widely distributed, the latter proving the most vigorous grower of any Olive yet in the state, although perhaps not so hardy as some others. A number of varieties of Mulberries, including the best Japanese, have been distributed at the various stations. They have done remarkably well. At Paso Robles they have resisted the hot and dry weather better than any other deciduous trees.

The Huasco raisin Grape, from Chili, has been distributed widely, and during the last two years has fruited in many parts of California. In appearance it seems impossible to distinguish it from the Muscat of Alexandria, but it shows less tendency to "coulure" in localities where this is caused by the northers, and hence may prove more valuable in certain regions.

Of new hardy Palms, the *Erythea edulis* is an attractive Pacific Coast species, similar in growth to the *Washingtonia filifera*, of a darker green, and without filaments. It has proved as good a grower and fully as hardy, having fruited for the past two seasons at Berkeley. The Chilean Coquito (*Jubaa spectabilis*) is much like the true Date Palm in appearance, but is of a more robust habit, and a darker green. It is also hardy here, and exhibits in Berkeley fully as good a

growth as the Date. The *Acacia Arabica*, one of the sources of gum arabic, was grown from seeds imported from India, and was distributed both in the form of seed and plants. The only place where it survived the severe winter of 1887-'88 was on the mesa land of San Diego County.

The New Zealand Flax, *Phormium tenax*, has been distributed throughout the state, and finds great favor with many gardeners for tying purposes. It does not thrive in the hot interior valleys, but in the Coast Range-region it is an entire success. In fact, I have seen it growing in cañons where roots have been thrown from gardens, and it is likely to become naturalized in some localities.

The University has devoted a good deal of time and money to experiments with new forage plants, medicinal plants adapted to the climate, and new fruits. E. J. Wickson made a valuable report on the grasses and forage plants in 1887, in which he said that this department began in 1879 with about fifty species of grasses, clovers and other plants, and had added all the promising species that could be obtained. The seasons of 1888 and 1889 were "dry years," and the conclusions of the previous years were confirmed. *Sorghum Halepense*, the evergreen millet, needs irrigation, will stand little frost, and has generally proved disappointing. Two Brome grasses, *Ceratochloa unuloides* and *Bromus inermis*, have been widely distributed with great success on hill lands. Of the Australian Salt Bushes recommended by Baron Von Mueller, *Atriplex vesicarium* and *A. nummularium*, the latter proves superior. It grows on salt marshes and affords much fodder. The Tegasate of the Azores, *Cytisus proliferus*, is a very pretty shrub, six to ten feet high, but its value for live stock is as yet unsettled.

The native grasses, clovers and forage plants of the Pacific coast are being tested under cultivation as fast as they can be collected. This is probably the most promising field at present. Only the old pioneers, who remember California and Oregon as they were when first settled, can form any idea of the waste wealth of pasture. Intelligent cultivation ought to restore the worn-out hill pastures of this region. In the years following a great rainfall, such as the present winter, species of native grasses and flowering plants that one seldom sees are abundant on the California hill-sides. The coming summer will afford an excellent opportunity to secure seeds and roots.

Niles, Cal.

Charles H. Shinn.

Viburnum pubescens.

Viburnum pubescens, figured on page 125, is one of the handsome North American shrubs which is not at all new from the point of view of science, but about which gardeners know very little, and no portrait of it has been published before except a small figure in a Danish scientific periodical practically inaccessible to the great majority of students.

Viburnum pubescens is, nevertheless, one of the best garden plants of its class. It is a compact shrub, growing in cultivation to the height of three feet or a little more, with rigid, erect branches covered with bright colored, reddish brown bark. The leaves are ovate, taper pointed, remotely and sharply serrate, except near the base; they are conspicuously pinnate-veined, two to three inches long, an inch or so broad, and are borne on short, broad petioles. They are covered, on the under surface, as are the young shoots, with a short and very soft pubescence; and in the autumn they turn to a peculiar dark and very rich purple color. The small flat cymes of white flowers, produced in great profusion, unfold in June, and quite cover the upper branches of well cultivated plants. The fruit ripens early, in September or even in August sometimes; it is very dark purple or nearly black. The drupe is oval, a third of an inch long, and slightly flattened before it is fully grown. The seed is slightly furrowed on the two faces with narrowly incurved margins.

Viburnum pubescens is widely distributed from Lower Canada to the Saskatchewan country; it is rather common in northern New England, extends westward to Illinois, and has been found as far south as Stone Mountain, in Georgia. It is rare at the south, however, and is a real northern plant. It resembles in general habit the better known *V. dentatum*, except that it is smaller in all its parts; and it was formerly considered a pubescent variety of that plant, from which, however, it is now distinguished by its flat drupes and seeds and by its short-petioled or nearly

sessile leaves. The fruit, too, is much darker colored, and it ripens earlier, while the color which the foliage assumes in autumn is entirely different from that of all our other *Viburnums*.

The autumn coloring of the leaves of this *Viburnum* constitutes its principal value as a garden plant, and makes it a very desirable addition to the shrubbery, where the unique tints it assumes in October make it always a most conspicuous and interesting object.

C. S. S.

Foreign Correspondence.

London Letter.

Fragrance in Ferns has lately been the subject of much discussion in the London papers, largely by people who appear to know little about it. We have not yet reached the point of starting a limited liability company to turn this property in Ferns to profitable account, although leader-writers in some of the morning papers evidently think there is a "good thing" in this—to them—new discovery. At a meeting of the London Botanic Society, the Secretary drew attention to the strong, hay-like odor of a Fern which he called *Polypodium Wildenovii*, but which afterward proved to be the commonly grown *P. Phymatodes*, the fragrance of which is well known to pteridologists. The odor is emitted by the fronds of this species when they are partially dried, and even after they have been dried for years. A few of the fronds, when placed in a room, impart to it a very pleasant, hay-like odor; or they may be used for placing among linen, etc. The plant itself is not in the slightest degree fragrant; it is only after the leaves have begun to "flag" that the odor is developed. There are several other species of *Polypodium* belonging to the same section as *Phymatodes* which also possess this peculiar character. They are employed by the South Sea Islanders and by the Maories in New Zealand to scent oils and various foods. It is possible they may prove of some economic value here; at any rate they may be used in preparing *pot-pourri*.

Other fragrant Ferns known here are *Dicksonia punctiloba* and *Nephrodium fragrans*, both natives of North America and both sweetly scented, the latter resembling Primroses in its odor. Then in England we have *N. æmulum*, called also *N. Fenisecii*, or "hay cutter," on account of its hay-like odor, and *N. montanum*, which smells like lemons. Another fragrant *Nephrodium* and a well known greenhouse Fern here is *N. patens*, the fronds of which when bruised emit a strong odor like that of ripe apples.

Although not fragrant, yet deserving of mention because of its strong and peculiar odor, is a variety of *Anamia Phyllitidis*, a common Fern in South America and the West Indies. As a rule this species is odorless, but I am informed that in Jamaica a variety occurs with a strong and very disagreeable odor. The development of this character in only a small proportion of the plants of a species is very remarkable. There is absolutely no other character by which the variety here called *Fœtida* can be distinguished from the type, except that of odor.

Seeds of Sugar Cane.—Two years ago attention was called to the question of how far it was possible to improve on the saccharine qualities of the Sugar Cane by other means than selection from bud variation, the plan invariably adopted by cultivators of this plant. It was then stated that "owing to the power of producing fertile seeds having apparently been lost by the Sugar Cane, it was impracticable to deal with it by means of cross-fertilization or by the ordinary course of seminal selection." This statement now proves to be incorrect, seeds and seedlings having been produced by Sugar Canes in Dodd's Botanical Station at Barbadoes. A quantity of the seeds have lately been received at Kew, and young plants raised from them. Apparently, therefore, the Sugar Cane still possesses the power to flower and mature seeds if placed under conditions favorable to its doing so. The importance of this discovery cannot easily be exaggerated, and there is now a hopeful prospect of a considerable improvement being made in the sugar-yielding qualities of the Sugar Cane, which, if realized, will strengthen the producers of cane-sugar against those of beet-sugar. That variation does actually occur amongst plants raised from seeds is proved by a letter from Mr. J. B. Harrison, of Barbadoes, to the Director of Kew (See *Kew Bulletin*, December, 1888, p. 294), in which he states that "sixty [seedling] plants were successfully transplanted and are being cultivated. At present they are not far enough advanced in their growth to speak with

certainly, but there appear to be amongst them several different kinds, probably five or six at least." A description of these six seedling varieties has lately been published in the *Demerara Garden, Field and Forest*, and they are spoken of as very promising. The Director of Kew has recommended the whole subject to the consideration of the Colonial government, suggesting that experimental cultures of the Sugar Cane should at once be started in Demerara, Jamaica and other sugar-producing colonies. The belief that the Sugar Cane never produced seeds also exists with respect to several other cultivated plants, two of them being natives of New Zealand, namely, *Convolvulus chrysorrhizus*, the Kumara of the Maories, the tubers of which are a staple food with them, and the Ti plant, a species of *Cordyline*. The former plant used to be in cultivation at Kew, and one year it produced tubers

English market. The French apples in the market now are remarkable for their bright, attractive colors, and they fetch about from twelve to sixteen shillings per hundred-weight, wholesale. The American samples vary in quality, the poorest selling for twelve shillings, the best for about twenty-five shillings per barrel. They are chiefly Greenings and Russets, the latter commanding the highest prices. Good grapes sell for as much as five shillings per pound. Oranges are abundant and cheap. Pecan-nuts from America have lately appeared in the London shops, and they promise to become almost if not quite as popular as their allies, the Walnuts. They are, however, not yet much known. The Shell-bark Hickory-nut also has been tried, but it is a very inferior nut and scarcely likely to find favor here.

Vegetables are abundant and good, the mildness of the win-

Fig. 26.—*Viburnum pubescens*.—See page 124.

which were quite as good as Parsnips, when cooked. They are, however, difficult to keep through the winter, and they were consequently lost.

Fruit and Vegetables in the London Market.—A few notes on these at the present critical season of the year may be of interest to some of your readers for purposes of comparison. With regard to fruit the supply is unusually poor, even for February. Pears are not to be had, while apples are rather scarce, what we have being either American or French, a few only being English, principally of Dumelow's Seedling, an Apple of first-rate quality and usually plentiful at this time of year. It and Bramley's Seedling, a very similar kind, are placed in the first rank and strongly recommended for orchard planting, the last named being spoken of by one of our first authorities, Mr. Wright, as superior to most of the apples grown for the

ter having been in the favor of growers, although the abundance tends to keep the prices exceptionally low. We have still Brussels Sprouts; Broccoli, chiefly from Cornwall, is plentiful and sells for about five shillings per crate. Kale and Sprouting Broccoli are also good and cheap, the last named being obtainable for one shilling per sack, the price of Turnip-tops, a popular vegetable here with the poorer classes. Savoys, bunched greens and Spinach are almost given away, the last named not commanding more than one shilling six pence per bushel. Potatoes are mostly of the following kinds: Beauty of Hebron, an excellent potato both for early and late purposes; Magnum Bonum, Early Rose, Regents, Scotch Champion and Emperor. These are more or less abundant, and vary in price according to quality from forty to seventy-five shillings per ton, a few specially good samples of Magnum

Bonum and Beauty of Hebron fetching as much as ninety-five shillings per ton. Asparagus fetches from eight to ten shillings per bundle of one hundred sticks. Tomatoes are now received from the Canary Islands in considerable quantities, and these are cheap enough and of sufficiently good quality to destroy the market for English grown fruit, which, a little while ago, sold for high prices at this time of year. Now, however, it is possible here to get a dish of tomatoes for six pence per pound retail. Except where otherwise stated all the prices here quoted are wholesale. I am indebted for most of the particulars here given to a paper by Mr. Shirley Hibberd in the *Gardeners' Magazine* of to-day.

London, February 22d.

Cultural Department.

The Cucumber.

THIS is a much more interesting study in a botanical sense than the Watermelon, and has a greater climate range than the Watermelon or Cantaloupe. It is eaten young as a pickle, older as a salad, and may be cooked at maturity like a squash. Each country appears to have its special varieties, some of which are not edible; others are actually poisonous, and others again are eaten with relish undressed.

The fruits vary in length from less than two inches to six feet, and from an ounce to twenty pounds in weight. Their prevailing color is green; but there are also white, yellow, pearl color with green stripes, and striped green and white varieties. In form they are straight, curved, tortuous, cylindrical and prismatic; with smooth, hairy, prickly, spinous and knobbed surfaces. Some are full of spines when quite young, and others like a hairy caterpillar; but both kinds become smooth as they mature.

Hairy Cucumbers are the favorites of Egypt and Syria, where they are eaten in vast quantities, as our people eat apples, without any preparation or even paring. In India they are used for pickling. We have tested two varieties from Cairo, and one from Beirut. One of the Cairo varieties is long, drupe-shaped, of a delicate pearl green tint, and has ten bright green lines running from end to end in shallow grooves; it is a beautiful looking fruit. The leaves of the plant are three-lobed and of small size; the fruit is known in Egypt as the Quaté. The other Cairo variety bears a curved fruit of much less attractive appearance, and the leaf is scallop-edged. The Syrian hairy Cucumber is known by the native name of Mukte, and is considered the best in Palestine, where they grow also pure white fruits, and green ones that turn lemon-yellow at maturity. The Mukte somewhat resembles the Quaté, but has the green lines only at the ends; its leaves are of the form of a Palm-leaf fan, and the plant looks more like a Cantaloupe than a Cucumber-vine. The natives eat this cucumber in quantities, skin and all, and American residents claim that it is much more wholesome than any of our varieties; when grown climbing it is a beautiful fruit, but is apt to grow hollow in our soil and climate.

The reticulated Cucumber has within a few years become well known by its sponges, sent as a commercial product in bales from Japan and Egypt. The first sold here was the product of the wild variety of Cuba, which grows very small in that island, but larger in Florida and in this city. The Cuba sponge is very fine in texture and only about eight inches long; it is used by Florida ladies for washing their hands.

The Chinese and Japanese have the largest of the Cucumber family, the fruits being very thick in proportion to their length. Seeds of the Chinese variety were sent to me under the name of a long, green Squash, by a correspondent at Foochow. I at once found that the fruit could not be a Squash, and was curious to find out what the peculiarly formed seeds would produce. The plant proved to be a Cucumber-vine of large proportions, having a leaf like that of the White Spine, but larger. The fruit is large and green, and would be taken for a Squash, which it tastes somewhat like when cooked; it hybridizes readily with our Cucumber, which ruins the product of the seed.

The *Benincasa cerifera* of India is an intermediate in character between the large Chinese Cucumber and a Watermelon. The vine is somewhat like that of a Squash, and the young fruits are covered with hairs; the seeds are white, very light in weight and abundant. The fruit looks like a Watermelon covered with a white coating like the bloom upon a blue plum, but much thicker; it is sometimes called the "Waxed Squash" and is prepared for the table by stewing; the seeds are much more like those of a watermelon than of a squash. The fruit has

been grown at Reedland Farm, New Jersey, and bears our climate well; I do not know that it has been cooked in this country; in India it is served at weddings.

Prompted by a remark made by an Armeno-Turkish lady, I sent to Constantinople and obtained in 1883 the seeds of a green cucumber, to which I gave the name of the "Pera," and which I believe to be the largest and finest flavored variety ever introduced into America; and this appears to be the opinion generally held in regard to it. I also obtained seeds of the White Cucumber of Palestine, and the prolific Green Cucumber of Malatiyeh, in the valley of the Euphrates, both of which were fully tested, and the former of which is considered a valuable acquisition for quality and productiveness. —From an address before the *Pennsylvania Horticultural Society* by Robert T. Harris, M.D.

Wire-Netting in the Kitchen-Garden.

PEAS, Climbing Beans and Tomatoes are all better for some support, and with most village-gardeners Bean-poles and Pea-brush cost money and trouble. At best, the brush and poles are unsightly. Some months ago I recommended the use of the galvanized wire-netting, now sold so cheaply for this purpose, and I have just seen the suggestion ridiculed in an agricultural paper as a device for millionaires. Now the fact is, that the galvanized wire-netting, sufficient for a row of Peas, Beans or Tomatoes 150 feet long, will cost twenty cents a year if ordinary care is taken with the netting when not in use. To go into the country, cut and haul brush enough for such a row would cost the average town gardener five times as much at least. In fact, I believe that in a farmer's garden even it will be more economical to use the wire than to take time to cut and haul the brush. In using the wire only a few stout stakes are needed, which can be put away under cover when not in use, and it makes the neatest kind of a trellis imaginable. It throws no shade and always presents a point to tie to. Tomatoes usually need a good deal of tying with most methods of training, but on the wire-netting they soon get their shoots interlocked in the meshes and only need the occasional tying in of a branch. This netting is not only cheaper than the various patent trellises offered for sale, but is much better every way. The netting is largely used for poultry-yard enclosures. A wider grade is used, so as to make a fence seven feet high by the help of a base-board twelve inches wide. There is no reason why these poultry-yard fences could not be made both beautiful and useful by using them to support Grape-vines, trained high, so as to have the fruit out of the way of the poultry. The vines would be benefited by the dropping of the fowls, and the fowls by the shade of the vines. I have often thought the hideous wire fences, which are now getting so common, could be made more useful as fences and at the same time yield a revenue by planting some of the improved Blackberries beside them and tying the shoots to the wires. I saw one recently covered with a dense growth of evergreen Honeysuckle, and it was about as pretty a hedge as one would wish to see. One of the beautiful sights of this city is a wire fence dividing two lawns, which is covered with well trained *Maréchal Niel* Roses. Northward a more hardy Rose could be substituted.

Raleigh, N. C.

W. F. Massey.

Beaumontia grandiflora.

BEAUMONTIA is a small genus of stout evergreen climbing shrubs with large leathery green leaves and terminal cymes of large, trumpet-shaped, white, fragrant flowers. It belongs to the same natural order as *Dipladenia* and *Allamanda*, namely, the Dogbanes, and with them forms a trio of free-flowering stove plants of exceptional size and beauty. But whilst the two last named genera are cultivated in almost every good garden, *Beaumontia* is scarcely known. The largest flowered species is *B. grandiflora*, and it is to this that we wish to direct special attention now.

It was first introduced into England by Dr. Wallich in 1818 from the Himalaya, where it extends from Nipal to Sikkim, ascending to 4,000 feet elevation. It does not, however, appear to have attracted the attention of horticulturists, and when several of its magnificent clusters of flowers were sent from the garden of Earl Cowper to a meeting of the Royal Horticultural Society, in the spring of 1886, it was almost unknown. Mr. Ruffett, gardener to Earl Cowper, has just forwarded to Kew an exceptionally large cluster of the flowers, and they are so large, so exquisite in form and purity, as well as being very fragrant, that one wishes that every garden possessed the plant which may be made to yield every spring flowers like these. Here is a description of them. Each flower resembles

in form and size the Bermuda Lily; the tube is six inches long, trumpet-shaped, two inches across at the mouth, where there are five spreading segments, each two inches long and one and a half inches wide, reflexed and pointed at the tips. The whole of the corolla is pure shining white, except at the base near the calyx, where it is slightly tinged with green. The calyx is composed of five oblong overlapping lobes, free almost to the base, one and a half inches long, green, tinged with brown. There are four fully expanded flowers, three large buds, and about thirty smaller ones in the single cymose head before me now. The leaves are ten inches long by about four inches broad, Magnolia-like in texture, dark green above, paler and tomentose beneath. The thickness of the stem six inches below the head is a half inch in diameter.

The plant grows very rapidly, and when properly treated it develops all along its main branches lateral branchlets, which, when about eighteen inches long, bear each a head of flowers. I have seen a plant which was growing in a stove, and planted in a fifteen-inch pot, with over a hundred flowers expanded upon it, and all upon a vine not more than twenty feet in length.

CULTURE.—I cannot do better than quote here the cultural directions which Mr. Ruffett sent to me a year or so ago. Speaking of the first small plant he got, he says: "I potted it in a compost of equal parts fibrous loam and peat, with a little

is something to know that this magnificent Indian plant is satisfied with our weak sunshine, provided it is left alone to make free growth in its own way."

There are three other species of *Beaumontia*, and one of them, namely, *B. Ferdoniana*, a native of the Deccan Peninsula, is in cultivation at Kew, and in a few other gardens, notably at Panshanger, where Mr. Ruffett has succeeded in flowering it this year. It is smaller in all its parts than *B. grandiflora*, and although handsome when compared with many other garden Apocynads, it is very second-rate by the side of its congener. The flowers last well when cut and placed in water. They are also suitable flowers for wreaths and bouquets. A wreath formed entirely of the flowers of *B. grandiflora* was one of the most beautiful of the hundreds sent to the funeral of the Duchess of Cambridge about a year ago. The majority of those who saw this wreath mistook the flowers for "elegant and uncommon looking Lilies."

Kew.

Orchid Note.

Maxillaria lepidota.—Under this name there is a small but vigorous plant now flowering freely in one of the green-houses at the Harvard Botanic Garden. It is uncommon and interesting. Brown, in his supplement to Johnston's

Clermont on the Hudson.—See page 122.

silver sand, keeping it in active growth. When it had attained the height of three feet it was planted out at the warm end of a large conservatory, where it grew fairly well for three years, but made no sign of flowering. Feeling assured it required more solar heat to develop its growth, I had it removed to the back wall of a Banana house, which is a span roof resting on a wall ten feet high. It was now a plant considerably over twenty feet high, and in a place that rendered it difficult of access. The consequence was that it was much mutilated in process of removal; so much so that I quite despaired of success in the operation. However, the thing was accomplished, and when a year had gone by it began to make rapid growth, and had to be stopped back to prevent its overgrowing everything.

"The use of the knife was evidently not to its liking, for it still made no sign of flowering. I therefore allowed it a space under the north side of the roof to grow as it liked, and then the tables were turned, and I had my reward for humoring its nature. In the following spring, after one year of free growth only, it made a grand display of flowers, and has continued to do so, the present being the third year of its flowering with me.

"I find it a very free-flowering plant, not requiring a great amount of fire heat, but all the sun-heat and light possible. It

"Gardeners' Dictionary," states that it was introduced from Colombia in 1878. But a species under the same name was known to botanists much earlier. Lindley's description of the latter is as follows: Stemless. Leaves solitary, strap-shaped and very sharply narrowed to a petiole. Peduncle one-flowered, acutely sheathed, erect and half as long as leaf. Sepals long, linear and narrowly pointed. Petals bristly acuminate and half as long as the sepals. Lip fleshy, obovate, three-lobed, keeled at top and chaffy on both sides. Middle lobe ovate; the top and anterior margins of the lateral ones crenate. Tubercle narrow and scarcely reaching the middle of the lip.* Now, the plant under notice differs in one very important particular from that described by Lindley. The latter is stemless, while the former has very apparent pseudo-bulbs, of flattened ellipsoidal form, and from two to three inches high. The solitary leaves are borne on top of pseudo-bulbs. In all other particulars our plant conforms closely to Lindley's. As a garden plant it is very desirable. The principal fault with many species of this genus appears to be that their flowers—borne, as they are, upon short stems—are hidden by the leaves. That, however, cannot be said of this one. The leaves droop over gracefully, and the flowers, being borne at the top of long stems, are

* *Annals of Nat. Hist.*, vol. xv., p. 38; 1845.

seen to full advantage. The flowers are of an orange-yellow color. The sepals are slightly marked with reddish brown at the base, on the outside; and an indistinct shade of the latter color prevails in about two-thirds of their length, measuring from the tip. The column is freely dotted with little brown spots. Delicate markings of the same color appear at the base of the lip, on the under side, and the thick keel is tipped with a conspicuous blotch of darker tone. Both sepals and petals are sometimes curled and twisted in a manner that renders them additionally interesting. As grown here, in a pot, the plant succeeds admirably under the treatment ordinarily accorded *Maxillarias*, and flowers freely during the winter months. Mr. Watson, of Kew, will confer a favor by saying how far this plant resembles any there may be, under the same name, in the Kew collection. Acknowledgment is made to Dr. Watson, of the Harvard Herbarium, for assistance rendered in my inquiries as to the identity of this plant.

Botanic Garden, Cambridge, Mass.

M. Barker.

The Day Lily of the Desert.

ONE of the most beautiful and characteristic plants of the Desert region of California is the Day Lily (*Hesperocallis undulata*). Its flower-stems rise from one to two feet above the sand, and bear from a few to thirty or more fragrant flowers, in color, I should judge, of a pearly or greenish white, with greenish stripes. I have seen only one in blossom, and that was too far gone to show the genuine tint.

This interesting species is one of the most promising novelties of the present season, not only for its promise of furnishing us with another lovely garden-flower, but also for its probable economic value in the arid regions of the west. It produces a large edible bulb, varying from one to four inches in diameter, nearly round, with firm flesh. The bulb has a pleasant taste, eaten either raw or cooked like onions. Our party of seven have had them cooked at nearly every meal since we first tested their qualities, and in the lack of other vegetables find them acceptable.

The bulb is found from six to eighteen inches below the surface of the sand or fine gravelly soil, in which the plant thrives best, and is usually found resting on moist gravel or a clay subsoil.

It is not rare on the Colorado and Mohave Deserts, and usually blossoms on the Mohave in the month of May. Near the boundary line it bloomed in 1889 as early as February, and was in seed in April. This year only a few plants are found showing as yet any signs of a flower-stem, but a few weeks of warm weather will doubtless bring them forward.

The Indians are said to obtain both food and drink from this plant when crossing the plains. For eighty or a hundred miles along our southern border one may travel at certain seasons without finding water. The traveler is safe, however, if he knows how to search successfully for this important vegetable, and once found he need not fear either hunger or thirst.

Should it prove susceptible of easy cultivation in the arid regions of the west, it will prove a valuable addition to our list of vegetables. It will certainly prove a welcome addition to the garden, if not an acquisition to the farm. C. R. Orcutt.

San Diego, Cal.

Clivia (Imantophyllum) cyrtanthiflora.—There are now many splendid hybrid forms of this genus, but it is doubtful if any of these will, for general purposes, prove superior to the subject of this note. And, by the way, this, too, is now classed as a supposed hybrid between *Clivia miniata* and *C. nobilis*, both natives of the Cape of Good Hope. Some years ago *C. cyrtanthiflora* was also regarded as a species from the same part of the world, and it would now be interesting to know why botanists have changed their minds. It is an evergreen bulbous plant that thrives most satisfactorily in an ordinary greenhouse. The pointed, strap-shaped leaves, from one to two feet in length, are arranged in two rows, and they all proceed from the root. The erect scape is almost as long as the leaves, and bears, in the form of an umbel, from twenty-five to thirty cup-shaped flowers, which are from two to three inches long, drooping, and of a bright salmon color; they are produced at various periods throughout the year, in fact, the plant is seldom without flowers, but most freely during the winter months, and their full color and freshness are retained a great while. Established plants seldom require repotting, and they may be grown in a cool greenhouse during summer, when they should be liberally watered; in winter water may be partially withheld, and the temperature should be maintained at about sixty degrees. To increase the stock, divide the old plants after flowering; and in potting use four parts of good rich loam to two of leaf-mould and one of rough charcoal.

Cambridge, Mass.

B.

Viousseuxia Pavonia, or, as it was first called, *Iris Pavonia*, is one of those charming old-fashioned plants which has now almost disappeared from gardens. It is a native of the Cape of Good Hope, like the other species of the small genus to which it belongs, is distinguished from *Iris* by its filaments united into a tube and by its minute interior perianth-segments. It is a greenhouse plant, but requires very little artificial heat, and flowers in February in a temperature running down to forty or forty-five degrees in cold nights. A pan filled with one or two dozen bulbs is an attractive object when the plants are in flower. They have long, grass-like, pendulous foliage, and flower-stems a foot high with wiry *Iris*-like flowers about the size of silver dollars. The three outer divisions of the perianth are white, with a large, conspicuous blue spot at the base, its margin fringed with purple and marked at the bottom with two bands, the first purple and the second yellow, the whole resembling the eye in the tail-feather of a peacock—a resemblance which caused the adoption of *Pavonia* as the distinguishing name for the plant. The under side of these divisions of the flowers are beautifully marked with reticulating blue or light purple lines. The Peacock *Iris* is one of the easiest plants to cultivate successfully. The bulbs multiply rapidly, so that the stock can soon be increased, and the plants had in flower during a considerable part of the winter if they are brought forward successively in different temperatures. It is not easy to explain, therefore, why such a pretty and desirable plant should have become so rare. It was one of the first plants from southern Africa known and cultivated in Europe and several figures of it appear in the botanical and horticultural literature of the last or of the beginning of the present century. Bulbs can be obtained from the bulb-growers of Holland.

Boston.

S.

Doronicums.—Mr. John Thorpe has done well to call attention to these desirable plants for winter blooming. Some twelve months ago I wrote of the value of *D. Caucasicum* for cutting purposes, and to this should be added *D. plantagineum excelsum*, the flowers of which are often four inches in diameter. Our plants have flowered for the past two months in a house where frost was excluded. In cases where this cool treatment is given the plants do not seem to suffer in any way when planted out in spring, but flower right on through the early summer months if placed in a rich, moist soil. With us *D. Clusii* is not a success, owing to its provoking habit of rotting in the centre, by which the plant is often completely destroyed. This has been our experience during the past two years with *D. Clusii*, both in-doors and in the open ground.

Dianthus latifolius.—There are not many perennial *Dianthus*es that will flower in four months from sowing the seed, but we sowed a packet of seed of *D. latifolius* about the end of September and the plants began to flower early in the new year. In habit this *Dianthus* resembles the Sweet William (*D. barbatus*), but the foliage is much broader, and the flowers are an inch across and are produced in clusters on long stems, so that they are very useful for cutting purposes, especially so since the unopened buds expand in water. We know of no *Dianthus* with flowers of such a brilliant, rich crimson as those of *D. latifolius*. It is a desirable plant where winter flowers are required in quantity.

Passaic, N. J.

E. O. Orpet.

Italian Onions.—The introduction of this vegetable has been a great boon to all the southern sections of our country, where the varieties usually grown at the north will not make a crop the first season from seed. Since these Onions have come into use there has been a large falling off in the quantity of Onion "sets" used, and the practice of using sets will soon be abandoned, at least with those Onions which produce seed. Those who grow the Italian Onions only from spring-sown seed, however, have no conception of the size they will attain if sown in autumn. How far north fall sowing can be practiced I cannot say, but whenever it is practicable to carry the crop through the winter the autumn is the time for sowing. The Giant Rocca Onion, which is very unsatisfactory from spring-sown seed, attains a size, when sown in fall, which fully justifies its name, and the large Tripoli sorts are immense. Here (latitude thirty-five degrees forty-seven minutes) we sow the seed at any time in October. Northward an earlier sowing would be better, so as to get the roots quite strong before winter. Here bulbs and tops grow all winter, and as the bulbs gain their size before extremely hot weather comes on, they reach a development which we cannot get with other sorts.

For family use and particularly for pickles the little White Queen Onion is unsurpassed. With this variety we can in

this latitude raise two crops in one season. It is best sown in February or March, as it matures very quickly, and a second crop can be sown here last of August and make good bulbs before Christmas.

The Striped Cucumber Beetle.—In my gardening experience of over thirty years I have never found any need for protectors to keep the striped bugs off of Cucumbers, Squashes or Melons. These beetles usually attack the plants when in the seed-leaf state, and seldom do much harm afterward. As soon as the seed-leaves appear the bugs appear also, but a handful of bone flour dusted over each hill will keep them away. One application usually suffices, but if washed off at once a second dusting will be needed. This is not only less trouble than boxing over the hills, but the bone flour is a good fertilizer, and stimulates the growth of the plants, so that they are soon out of reach of the beetles. Devices to protect plants from the weather are useful, but bug protectors are unnecessary, in my judgment. *W. F. Massey.*

Correspondence.

Park Construction.

To the Editor of GARDEN AND FOREST :

Sir.—Every landscape gardener who has had much experience in the creation of parks understands that his work is but half done when he has completed his design. However carefully he may have prepared his plans, detailed specifications and instructions, he knows that the result depends upon the skill of the man who has charge of the construction. It is rarely the case that the designer is allowed to exercise more than an occasional supervision of the work. Having furnished working plans drawn to scale, lists of trees and shrubs, with explanations of all matters that cannot be represented in drawings, his duties are supposed to be finished, and the work of construction begins under the direction of an engineer or a superintendent, who is employed by the park commissioners and is subject to their direction. The designer ought, of course, in all works of importance to supervise the construction, for there is always much that is essential in carrying out details, which can by no possibility be represented on a plan or described in words, but must be directed on the ground by the artist's eye. This, however, at least in the west, is often impossible, or rather impracticable.

Park commissioners in this section, as a rule, are unwilling to incur the expense of such supervision, and having secured the plan, they leave it to the superintendent and the engineers to transfer it to the ground. Not infrequently the work of grading, road making, etc., is let out to a contractor and the tree planting to the man who will do it at the lowest cost. The result in either case is sure to be unsatisfactory, and if it is further complicated by the officious interference of some prominent member of the Commission who has a local reputation as a connoisseur in art, it is probable that a large amount of money will be wasted on artificial decorations, which are utterly incongruous and destructive of the effects of the original design.

There is but one way in which the work can be satisfactorily performed, and the all-important person to ensure such performance is the park superintendent. I speak confidently on this point, from having in repeated instances witnessed the worse than useless expenditure of large sums in the effort to economize by dispensing with the services of a skilled superintendent, or by employing an incompetent man because he could be had at a low price.

It is all-important in the first place that the superintendent should be a manager of men and able to work them advantageously; for otherwise thousands of dollars may be wasted in loss of time or inefficient work. Where hundreds of teams are employed, a load or two more or less in a day's work of each one becomes a matter of hundreds of dollars before the week is out. And so of every item of the work performed. These are the costly leaks. A competent man will secure from every employee the full amount of his labor, and without any appearance of needless crowding. But this is only one of the essential qualifications of a superintendent. He must be sufficiently familiar with park construction to appreciate the general effects intended by the design, and in directing the work of grading and road making, as well as in planting or removing trees, opening up woods, etc., he must work with steady and intelligent purpose to develop these ideas. He must know enough of soils and of tree planting to see to it

that all newly graded ground is provided with sufficient depth of fertile surface soil, and that all such soil, as well as other fertilizing material, is preserved, and that the trees after being properly planted are properly cared for. He will of course employ tree planters and gardeners, but he must himself be sufficiently skilled in the practice to know when each operation is thoroughly performed.

It is plain from these considerations that a capable superintendent may save to a city in a single week more than the difference between his year's salary and that of an incompetent man; and yet it is almost invariably the case that a board of park commissioners is beset by candidates who are ready to work for a low salary, and such a man is often selected from fear that they will be charged with extravagance if they employ a man who knows his business and demands what his work is worth. In the course of forty years' experience as a landscape-gardener, I have had such repeated evidence of the "penny wise, pound foolish" policy of employing cheap men, and such opportunity of enjoying the results of a wiser course of action, that I take this method of presenting the matter for the consideration of every one who is interested in parks and their construction.

A Northern Station for *Quercus lyrata*.

To the Editor of GARDEN AND FOREST :

Sir.—On the 13th of September last, while gunning in the bottoms of the Patuxent River, about three miles below (east of) Laurel, Maryland, I was surprised to find myself confronted by an old acquaintance in several trees of *Quercus lyrata*. The tree was rather common there, growing along the banks of shallow "sloughs" and in other wet situations, the trees associated with it being *Q. Michauxii*, *Q. bicolor*, *Ulmus Americana*, *Liquidambar styraciflua*, and several others which thrive best in wet locations, with *Fagus ferruginea* in the immediate vicinity. While the *Q. lyrata* was fairly common, it was of small size, none of the trees much, if any, exceeding thirty or forty feet in height.

Before finding this species, I had been struck with the exceedingly close resemblance between the tree growth of the locality and that of our western bottom-lands, there being but three species (*Quercus phellos*, common, and *Ilex opaca* and *Juniperus Virginiana*, rare) among the twenty-three species growing there which were not common to the two regions! Of course many western types, or those which are more common west (as *Tilia*, *Æsculus*, *Negundo*, *Gymnocladus*, *Gleditschia*, *Cercis*, *Catalpa*, *Celtis*, *Juglans*, *Populus*), were wanting, but the general facies of the silva and manner of growth were exceedingly similar, *Asimina*, *Liquidambar* and *Liriodendron* being very common.

It is interesting to note that this station of *Quercus lyrata* is almost exactly on the same parallel of latitude (near thirty-nine degrees) as the locality where I found it in the summer of 1888 in southern Illinois (bottoms of the Embarras River, Jasper County).

The note in a late number of GARDEN AND FOREST on the occurrence of *Tillandsia* in northern Tennessee reminds me that in the summer of 1880 or 1881 I found this plant on the eastern shore of Virginia, about midway between Cherry-stone and Cobb's Island landing. It was not plentiful, but I found several tresses of it hanging from the large Pine-trees (*Pinus Tæda*) and Hollies (*Ilex opaca*), by or near the road-side. This, I believe, is its most northern station on the Atlantic coast.
Robert Ridgway.

American Oaks in Belgium.

To the Editor of GARDEN AND FOREST :

Sir.—American Oaks have been introduced into Belgium comparatively recently. The oldest in the country are hardly more than a hundred years old. They thrive here admirably, however, and grow with astonishing rapidity in a light, sandy soil with a rather moist subsoil, the annual shoots often exceeding four feet in length. The Belgian government has of late years devoted a great deal of attention to plantations of trees along the highways. Our Elm (*Ulmus campestris*) injures crops in the neighborhood of the highways with its long superficial roots, and on this account has been largely abandoned in highway plantations; and where the soil is adapted to them, the Red and Spanish Oaks have been largely planted. In the province of Limbourg, where the soil is suited to them, thousands of these two trees have been used with the greatest success. The growth of the Red Oak

is marvelous. Trees only forty-five years old have an average trunk circumference at three feet from the ground of five feet eleven inches, and an average height of more than sixty feet. The actual money value of these trees is from six to eight dollars. In another plantation made in 1845 the trunks have an average of four feet eleven inches, and in still another made as late as 1852 they have an average trunk circumference of five feet three inches. If the development of the Red Oak continues to be as satisfactory in the future as it has been, we shall be able to show in Belgium trees at least three and a half feet in diameter and nearly one hundred feet tall.

The density of the wood of *Quercus rubra*, as compared with our native Oak, *Quercus Robur*, is: *Q. rubra*, 391; *Q. Robur*, 377. The comparison of these two totals shows that the wood of the American species is harder than that of the European. In the trials which have been made to determine the value of the wood of the American tree grown here, in carriage-building and in cabinet-making, its great value has been amply demonstrated. Where the native Oak remains dwarfed and stunted owing to a soil too light for its best development, the Red Oak grows with luxuriance; and its introduction into those parts of Belgium where the soil is light and sandy is a benefit which all land-holders now recognize; and it appears evident that in a few years the American Oak will have replaced the native species in many parts of the country.

Quercus palustris seems destined, like the Red Oak, to be a very useful tree here. There are plantations in this country already sixty years old, containing trees with trunks more than six feet in circumference. It appears, therefore, that this species grows more rapidly even than the Red Oak; and it is noticed that the trunk rises more rapidly than the trunks of other American Oaks. There are some beautiful plantations of this tree along the highways of Limbourg, admirable examples of luxuriant vegetation and promising the best results for the future. It is now proposed by the government to make trials with *Quercus tinctoria* and *Quercus Phellos*. Possibly these facts, the result of experiments in a foreign country, may have some interest for the American readers of your journal.

Mons, Belgium.

Alfred Wesmael.

The Waverly Oaks.

To the Editor of GARDEN AND FOREST:

Sir.—I have read, with much interest, the editorial in GARDEN AND FOREST for February 19th, upon the Waverly Oaks. I have met with no such interesting group of Oaks as these. Their location so near the picturesque cascade of Beaver Brook, and upon a supposed local terminal moraine, their grand proportions, their undoubted great age—all about them is worthy of marked attention. It seems to me that their destruction would be an act of vandalism. The suggestion which you emphasize, that the trees should be preserved by setting apart the ground containing them as a public park, is certainly a wise one; and if the park could include the "Cascade" with the glade below it, together, it would be one of the choicest bits of public ground in the vicinity of Boston.

It may not be inappropriate to quote the dimensions of a few White Oaks in Rhode Island, from data which I made and published ten years ago. One of these is on the Owen farm, in Pawtucket, in an open lot on the Power Road from Providence to Pawtucket. The tree has had opportunity for development in the open ground for a century or more, and it is noticeable for its great spread of ninety feet across. The six lower limbs are thrust out nearly parallel to the slope of the ground, and one of them is fifty feet long. The supporting power of these massive members must be enormous. The body is small in proportion to the size of the tree, being only nine feet in circumference at four feet from the ground.

Another remarkable tree stands just over the state line in Massachusetts at Munro's Tavern. In 1858 its circumference, three feet from the bottom, was sixteen feet three inches. There is a tradition, which seems authentic, that a company of soldiers, returning from service, camped about the trunk of this tree and spent the night under its protection. The Catholic Oak, at Lonsdale, girthed, in 1878, fourteen feet at four feet from the ground.

Providence, R. I.

L. W. Russell.

Prairie Forestry.

To the Editor of GARDEN AND FOREST:

Sir.—In a recent number of GARDEN AND FOREST appeared an article in which the writer held, very properly, that tree-planting is not forestry. And yet, in the vast prairie regions

of the country, where the need of forests is more apparent, though not so great in reality, as among the mountains, the sources whence all our great rivers flow, forestry must mean tree-planting for many years to come. To the people of the western prairies—the Dakotas, Nebraska, Kansas, Iowa and western Minnesota—the word forestry has become synonymous with tree-planting, and conveys no other meaning. It is indeed fortunate that this is so. The prairies can never know the primitive meaning of the word forestry until they cease to be wind-swept. Every year the treeless belt becomes narrower, through constant planting on its eastern border; and while it is true that the prairies will never be forested by the individual enterprise of the farmer, it is equally true that the whole aspect of the west has been changed within the past twenty years. Planted trees have clothed the naked landscape, and homes have been sheltered and the growth of fruit made possible. In crossing the state of Iowa from Dubuque to Sioux City the traveler sees a wonderful example of what forestry means on the prairies. In the eastern part of the state native woods abound along the streams, but after leaving the valley of the Cedar, plantations become a feature of the landscape. Every house seems embowered in trees, suggesting shelter and comfort for the inmates. Farther west these groves decrease in size and number until, beyond the Des Moines River, the prairies are almost as bare as they are in central Dakota. Every year the groves increase in number and in size, and if prairie foresters in Iowa continue to plant trees in the next decade as in the past, the state will have almost genuine forest conditions. It will at least have solved for its open prairies the difficult problem of protection from wind, and they may do much toward eliminating the disastrous droughts that have been such a burden to agriculture during recent years.

Brookings, S. D.

Chas. A. Keffer.

Populus certinensis.

To the Editor of GARDEN AND FOREST:

Sir.—Under this name we received from the Arnold Arboretum, a number of years ago, cuttings of a Poplar which promises to be very valuable on the high, dry prairies of the north-west and west, as it maintains perfect health of foliage and makes a clean, rapid, upright growth where the Cottonwood and other native trees of the bottom-lands of our streams utterly fail to live. I speak of it at this time, hoping to discover the origin of this name. I do not find it in Koch's "Dendrologie" or in any other work in our libraries, and it appears to be identical with, or very closely related to, *Populus Petrovsky*, as sent us by Director Arnold, of Moscow. It also appears to be very closely related to the species known in Russia as *Populus Wobsky*. As this tree has come to stay in the west, I am anxious to determine its origin and its correct name.

Ames, Iowa.

J. L. Budd.

Periodical Literature.

THE February issue of the Kew *Bulletin of Miscellaneous Information* contains an article on the *Manufacture of Quinine in India*, in which the new oil process for manufacturing sulphate of quinine is explained. The success of this process is a matter of some importance, for if Cinchona-alkaloids can be cheaply extracted from the bark at the place where it is grown, a great saving will be made in the cost of transportation to Europe and America. Mr. C. H. Wood, late government quinologist to the government of Bengal, in an appendix to this paper, sums up the chief advantages of preparing quinine in this manner as follows: "First, the alkaloids are completely extracted from the bark in a much greater state of purity, so that the final operations for obtaining pure and finished products are much simplified. Second, that the whole process of extraction can be performed at common temperatures. Third, that the apparatus and appliances required are all of a simple character and are well suited for use on the plantations."

The low price of Cinchona-bark, quinine and other Cinchona-alkaloids is explained by the immense exportation of bark from Ceylon. It is only a few years, comparatively, since the Cinchona-tree was first introduced into Asia through the efforts of the British government, but the quinine raised in the government plantations of Ceylon, India and Java already far exceeds the amount produced in the native forests of the Andes; and therefore regulates the price of the product.

The introduction and cultivation of the Cinchona in Asia is one of the most triumphant agricultural successes the world has ever seen, so far as the consumers of quinine are

concerned. Overproduction, however, has had the natural results with the planters, and quinine is now sold in London at prices considerably below the cost of production. This is due principally to the state of affairs in Ceylon, where the Cinchona was planted in immense quantities to replace the Coffee-tree, long the staple product of the island, when the coffee crop began to fail from the fungoid disease which attacked the trees. Then the Cinchona failed there to a certain extent, and the planters turned their attention to tea-planting, cutting down the Cinchona-trees by wholesale and throwing the bark on the market in immense quantities, and with fatal results so far as the price of the commodity was concerned. This state of things, however, sooner or later will correct itself, and the world owes a debt of gratitude to the authorities of Kew, through whose instrumentality the Cinchona-tree was first successfully transported from the new world to the old, for this successful piece of work, a good example of the practical value of a great scientific establishment of this character.

There are papers, too, on the use of the berries of the Maqui (*Aristotelia Maqui*) in coloring wine. The Maqui is a small evergreen tree or shrub, which is common in the mountain regions of Chili, belonging to the same family as the Lindens, and with the same fibrous inner bark. Maqui berries are eaten in Chili either fresh or preserved, and mixed with grapes are made into wine. Of recent years they have been collected and exported to Europe in very large quantities for the purpose of coloring wine. This industry seems to be growing rapidly. In 1884, 26,592 kilos of the dried berries were sent to France, while in 1887 the quantity had increased to 315,774 kilos. The berries are used in the same way and for the same purpose as Elder-berries have been used in France. The present issue of the *Bulletin* contains also shorter articles on *Vine Culture in Tunis*, on the *Phylloxera in Victoria*, on Baron Eggers' *Botanical Exploration of Cuba*, and a statistical article on the sugar production of the world, which, among other things, shows that for a period covered by the years 1853-1887, out of a total increase of production amounting to three and three and a quarter millions of tons, no less than two and a quarter millions of tons, or about sixty per cent., is an increase of beet-sugar, which has now changed its position as a factor in the production, having reached the point of being nearly equal to cane-sugar, whereas at the beginning of the period it supplied only one-eighth of the total production. The production of both British cane-sugar and foreign cane-sugar has more than doubled in the same period.

Bibliography.

A List of Works on the Art of Landscape-Gardening.

THE following list of works treating of landscape-gardening which have been published in English, French, German and Italian since 1625, the date of Bacon's classical essay, has been prepared in the library of the British Museum, in the Bibliothèque Nationale and in other public and private libraries, and is as complete as I have been able to make it. I have endeavored to include all books, pamphlets, articles and reviews except those which have appeared in horticultural and agricultural papers. Such a work is necessarily liable to error, and I shall be glad of any suggestions or corrections which will help to make the list more complete and correct.

Those books which seem to have a special interest are marked with a star.

Notes.

Eucharis Bakeriana is a new species which has recently flowered in England in the St. Albans nursery, and which has been named by Mr. Sander in compliment to Mr. Baker, of Kew. It has the foliage of *E. Amazonica* and flowers as large as those of *E. candida*; it differs from all other species in having a conspicuous trumpet-like corona, as in the Daffodils. As a decorative plant it is the equal of *E. candida*.

The first cost of stocking a Narcissus-farm in the Scilly Islands is almost prohibitory except to a capitalist. The roots can be had for ten dollars a thousand, but a single acre will easily swallow up a million roots. Ten thousand dollars for stocking one acre seems like an expensive plant, but the increase is such that three acres can be planted the third year, and so long as the demand for the flowers lasts this will prove a lucrative investment.

The market gardeners of the south, particularly those about Mobile, have suffered seriously this year from injuries inflicted by the cut-worm. Truck farmers were obliged to employ a force of men to begin work at early dawn to search for the destroyers and to set out new plants where the young Cabbages had been cut off. The farmers attribute the great increase in the number of various pests to the extermination of insectivorous birds by pot-hunters, and by boys and others who shoot them out of mere wantonness.

Successful experiments have been made in Austria for the conversion of corn-husks into paper and cloth. The husks are boiled in an alkali until the fibres are reduced to a spongy condition. The glutine is then pressed from the fibre, which remains as a mass of chain-like, long threads, interspersed with shorter ones. The long fibres are woven into a good quality of coarse cloth, similar to that made from the lower grades of flax and hemp; and the short ones make an excellent paper, very strong, and hard and firm in grain.

The Cornelian Cherry (*Cornus mascula*) of Europe is now lighting up the shrub-borders of Central Park with its golden bloom. It is surprising that so good a shrub or small tree is planted so little in this country. It should have a place wherever spring flowers are admired, for it never fails to bloom profusely. Later on, when in full foliage, and in late August, when its cornelian-colored, cherry-like fruits are fully ripe, it is a most attractive object. Up to the present time, moreover, it has escaped the ravages of the destructive larvæ of the Cornel Saw-fly, which was described and figured in vol. ii., page 520 of this journal.

Beyond Boma, according to Mr. Tisdell's interesting account of the Congo Basin in the *Century Magazine*, there is nothing at all in the valley of the Congo wherein he traveled which one could describe as a forest in any particular. While one does find some large trees, they are few, and principally Mangroves. Nothing indicates that there ever has been a growth of timber. In the first place the soil is not of sufficient depth or richness to produce timber or even to produce anything. About the only thing that grows along the valley is wild grass, sometimes ten, twelve, fifteen and even twenty feet high; and throughout the whole country are zigzag paths made by the natives and utilized by the caravans.

Harpers' Weekly for February 22d gives an illustration of the new gateway for Harvard University, recently built by Messrs. McKim, Mead & White, together with a reproduction of the design as at first proposed. It was noted in these columns about a year ago that this design showed a large central gate of wrought iron, flanked by stretches of wall in which were low, round-headed doors, and beyond these tall iron railings. As now constructed, the walls are solid and plain, and an iron gate, smaller than the central one, is placed beyond them on either side. The change is not an improvement; yet, as it stands, the entrance is both dignified and appropriate, and the treatment of the iron-work is described as particularly artistic and beautiful.

A lady writing from Michigan to the *American Florist* with regard to the rapidity with which bulbs may multiply if undisturbed for a few years, says: "I thought I would take one *Gladiolus* bulb and ascertain what the increase would be in five years. I selected Madame Monneret, . . . and in the spring of 1886 I planted one small bulb; in the fall of the same year I had one large bulb and over forty bulblets to plant out in the spring of 1887. In the fall of 1887 I had forty small but blooming bulbs, and, by actual count, 500 bulblets. In the fall of 1888 I had 500 small but blooming bulbs, and, by actual count, 4,500 bulblets. In the fall of 1889 I have 500 three-year bulbs, 4,500 two-year bulbs, and the bulblets I have

not had the patience to count, but thought 50,000 would be a low estimate. Next year would be five years, and I easily could have 50,000 bulbs if it were not for selling them as soon as they become marketable."

The municipal government of Paris has just purchased the Forestry Pavilion, of which an illustration was given in our issue of January 25th, paying the French Forest Department \$17,000 for it, and workmen are already at work preparing to remove the building from the Trocadéro to the Bois de Vincennes, at the other end of Paris. It is pointed out in the *Revue des Eaux et Forêts* that the city has made a foolish bargain. The pavilion was erected without permanent foundations, which will now have to be provided for it, and these and the cost of removal are estimated at \$2,000, making the cost of the building when set up \$19,000, which does not include any of the contents, which will have to be provided for in addition, as the Trocadéro exhibit is retained by the Forest Department. The great trouble, however, is not in the cost of the building, but in its temporary character, for it is shown that a building constructed of unseasoned logs, and dependent for its beauty upon the preservation of their bark in the natural state, can last at most only two or three years in a presentable condition.

The milder climate of England means a much earlier spring than ours and the later survival of a multitude of autumnal flowers, so that, in the southern counties at least, there is often not a week in the year when something pretty may not be gathered from the garden. But, on the other hand, our brighter winter skies are far more favorable to plants grown under glass. These facts were commented upon by Mr. Samuel Henshaw in an address recently delivered before the Florists' Club of this city, and the difficulty of forcing Roses in England was especially noted. "All through the middle of the winter," he said, "there is a great scarcity of this flower in England. Even Tea Roses are scarce and poor in quality." *Gloire de Dijon* Roses and a few varieties of Teas "were exhibited at the spring show in Bristol in March, but were few and very much inferior to what may be seen in any florist's window in the middle of the winter in New York." But in the southern parts of England the *Gloire de Dijon* "is often seen covering the fronts of cottages and in full bloom in the early part of May."

The production of Sisal hemp in the Bahama Islands is being rapidly developed, arrangements having been perfected lately to plant 10,000 acres with the Sisal under the stimulating influence of an export duty of £4 13s. 4d. per ton, paid by the government, on all Sisal hemp grown on the islands. Sisal hemp is produced from a species of Agave (*A. rigida*, var. *Sisalina*), a native of Yucatan, where it has been cultivated by the natives ever since the country was known to Europeans, and where of late years its cultivation has immensely increased on account of the growing demands in all parts of the world for larger supplies of Hemp than the East Indies have been able to supply. This great increase in the consumption of hemp-fibre may some day or other have an important influence on the agricultural prosperity of Florida. The climate, soil and vegetation of the southern shores and islands of Florida are identical with those of the Bahama Islands, and if Sisal hemp can be produced in those islands, it can be grown of as good quality, if not as cheaply, in south Florida, when it is known that the Sisal plant flourishes, and where it is now naturalized and spread over a considerable surface, it having been one of the useful plants introduced into Florida about fifty years ago by Dr. Perrine, who was employed by the government of the United States to study the economic value of various plants and test their adaptability for naturalization in Florida. He made a careful study of the Sisal in Yucatan, and the results of his investigations were published in Senate Doc. 300, Washington, March 12th, 1838. The principal crops of the Florida keys, of which only a very small part are cultivated at all, are tomatoes, grown to supply the northern markets in winter, and pineapples, which suffer during winters of unusual severity, and are not, so far as quality goes, a satisfactory crop. Extensive plantations of the Coconut have been made on the Atlantic coast; but although there are a few large Coconut-trees on Key West and near Bay Biscayne which yield fruit, it is doubtful if the climate of south Florida is sufficiently hot to produce coconuts which will be able to compete in the market with those grown under the more favorable conditions which prevail in Jamaica, British Honduras and Guatemala. Sisal is, on the whole, the most promising plant with which to experiment in southern Florida; and nothing but the cost of labor and machinery in Florida can interfere with the production of Sisal hemp in competition with that grown in Yucatan or in the Bahama Islands.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MARCH 19, 1890.

Street-Trees.

A YOUNG tree on the border of a city street can never be said to have congenial surroundings, even when the utmost pains have been taken at the outset to plant it properly and to give intelligent attention to its needs so far as possible thereafter. Many kinds of trees will absolutely refuse to live in an atmosphere filled with smoke and dust, even when the drainage system of the city does not rob their roots of the water which is essential to their nourishment. The hardships which a street-tree must undergo make it all the more necessary that only the most promising individuals of the kinds best suited to endure the trying conditions of city life should be selected. This means that nursery-grown trees, with abundant roots and pruned for the purpose, should invariably be used.

It is plain that trees of one variety only should be planted in a long, straight row parallel with the lines of buildings in a continuous street. Much of the desired effect will be lost if the trees vary in form or size, or expression, or rapidity of growth, or in the time of putting forth their leaves or shedding them. An avenue of American Elms, with their lofty overarching tops, is always beautiful, because the charm of each tree is renewed in the next, and the effect of the whole is constantly intensified and multiplied by repetition. An avenue of stately Tulip-trees is equally beautiful, but in an entirely different way. The same might be said of a double row of Pin Oaks, where there is space for their drooping lower branches. But if all these trees were intermingled, and Sugar Maples, Horse Chestnuts and others still were added, the result would be incongruous and contradictory. There would be no continuous lines extending through the entire vista to help the perspective and to give unity of character and expression and consistency of purpose to the whole. And yet in our city street-planting it is the common practice to allow each lot owner to select the tree which suits his fancy. The immediate effect is bad enough, but it grows worse as years roll on and the individual trees become more and more unlike each other as their peculiar characteristics are more strongly marked with age.

But even when the best selection is made, disappointment and failure will be the inevitable result unless the ground is properly prepared and the planting carefully done. A street grade is often made several feet below the natural surface of the ground, and of course this subsoil is not in a suitable mechanical condition to receive the roots of trees, nor does it contain the necessary nourishment. Or, again, a street may be raised as much above the natural level, filled in at the bottom, perhaps, with large rocks which have been thrown together so as to leave air spaces between them, and this open foundation may be covered with a stratum of all sorts of rubbish. No tree can be planted in such a situation with any promise of health or long life. In most cases, an excavation twenty feet across and three feet deep, filled in with good loam, will make a safe place in which to plant a tree, but even here the tree will be doomed to early death if it is just over such a foundation of broken rock as has been mentioned above. We might add that street-trees should always be planted far enough apart to give each one an opportunity to develop into its best proportions, but perhaps many persons who read this already feel inclined to resent the frequent iteration of these elementary principles. And yet there is hardly a city in the United States where every one of the ordinary, common-sense rules and precautions which should be regarded in planting street-trees is not almost constantly violated. The fact is, that this article was itself suggested by some planting in this city which recently fell under our observation.

West End Avenue, a broad street on the heights between Riverside and Central Parks, is laid out with a strip of turf some eight feet wide on either side between the sidewalk and wheelway. In each strip is a double row of trees, not planted in pairs, but alternately—that is, with one tree near the outer margin of the grass, and then another near the inner margin. The shortest or diagonal distance between these trees is about fourteen feet. They are Red Maple saplings, apparently pulled up from a swamp where they stood very closely, so that they had grown up straight and slender to a height of probably fifteen feet, with very few, if any, side branches. The tops were all cut off at a height of about ten feet, leaving bare poles above ground and a few of the larger roots below. These trees were planted in the autumn of 1887 and the following spring, and have, therefore, had two summers to grow in, but as a matter of fact there has been no growth. Clusters of little branches have been thrown out at the tops and at a few points on the sides of the mutilated stems, and these tufts of foliage may prolong the life of the trees for a time; but they are rather signs of approaching death than of life. Many of the trees are already leaning over and ready to fall. In short, here is a street nearly two miles long, planted with at least three times as many trees as should have been used—trees of a variety unsuited to the position they occupy, and not a single individual of them all a specimen well grown and pruned for this purpose. The city has paid some \$20,000 for this work, which is absolutely worthless—worse than worthless, indeed; for while these trees are dying, years are wasted in which good trees could have been making substantial growth, and even now they would have been delighting all beholders with their beauty, and still more with the cheerful promise of increasing attractiveness for years to come.

If this were an isolated instance it would be sufficiently depressing, but equally bad examples of contract-planting by municipal authorities can be pointed out in almost every one of our large cities. The streets of our towns and cities will never be shaded by handsome and well-cared-for trees until they are placed in charge of some competent and responsible officers, whose duty it is to superintend all planting, and all pruning, too; for now no street-tree, however beautiful, is safe from the attacks of axes and saws in ignorant hands, which not only destroy its symmetry, but leave it with raw wounds to invite the entrance of destructive fungi, which bring disease and premature death.

PROFESSOR KELLERMAN, in *The Industrialist*, quotes approvingly what was said in our issue of January 22d of the ornamental value of the Celtis or Hackberry, as it is usually called in the west, and he adds that in Kansas it has a greater relative value than in well-timbered regions, where so many kinds of trees grow in perfection. In the state, which includes a large portion of what was once known as the "Great American Desert," the Hackberry is one of the few trees which can withstand the drought, hot winds and other trying characteristics of that variable climate. Professor Kellerman, however, calls attention to the fact that the annual report of the Kansas College Experiment Station for 1888 gave a full account of an insect—a species of *Phytopus*—and of its invariably accompanying fungus (*Spherotheca phytotophila*, Kell. & Sw.), which are doing great injury to the Celtis in that region. The insect is a gall-mite and the fungus a species of powdery mildew, and they cause what is known as "Hackberry knot," an abnormal growth which seriously injures the health and appearance of the tree. The disease is said to occur in the eastern part of Kansas, and it extends westward as far as the forest-trees extend. It is also reported in Iowa. Professor Kellerman has not found the trees in the forest abundantly attacked, but most of the isolated ones are disfigured by the multiplying knots until they become very unsightly and finally die. No remedy has been experimentally determined upon except cutting off and burning the infected parts.

A figure of one of these knots is given in *The Industrialist*, and we refer to it because we have recently observed a similar appearance on many specimens of the Celtis in Central Park, in this city. A more careful investigation will be needed to identify this disease with the western one, but it is not improbable that trees of this species throughout the country have found a serious enemy.

Japanese Dwarf Plants at Paris.

IT is well known that the Japanese landscape-gardener prides himself on his treatment of areas so small that we should give them up to a gravel walk and a couple of Geranium beds. So it was a disappointment not to find, on the soil of the Japanese Horticultural Section in the Exhibition grounds at Paris, some illustration of his practice.

The Japanese Horticultural Section was only a small space on a rather steep part of the Trocadéro slope, surrounded by a rough bamboo fence which would doubtless have looked pretty amid consonant surroundings, but seemed a little slovenly and poor by contrast with neighboring French arrangements, which were scrupulously trim and durable looking. Almost the whole of the enclosed space was laid out in a series of low terraces, each of which bore a row of potted plants.

I was not wise enough to know whether any of these plants had especial interest for the European botanist. But I soon saw that some of them were extremely interesting to the cultivator and the student of art. These were the examples of dwarfed trees. We have become familiar, in our own gardens, with certain dwarf varieties of trees produced in Japan, as with many kinds of little Maples; but I speak especially of dwarfed specimens of individuals which, if left to themselves, would have been large, but which generations of gardeners had patiently restricted to the most exiguous proportions. These we constantly see in Japanese pictures, but there is seldom a chance to behold them alive.

In the *Bulletin de la Société Botanique de la France* some facts were recently given with regard to the method of their production, on the authority of two Japanese connoisseurs, one of whom was an exhibitor in Paris. The chief point is that the trees are grown in the smallest possible quantity of soil. The baby plants are put in pots so small that their roots soon fill them entirely, and, seeking further nourishment, break out above the surface. Then a somewhat larger pot is given, in which, however, the same want of sufficient nourishment soon produces the same result; and this treatment is perpetually continued. Moreover, only just so much water is supplied as is absolutely needful to preserve life. The main root thus becomes bent and the lateral roots develop neither quickly enough nor profusely enough for vigorous growth, and all the processes of life are very greatly retarded. The

roots are never cut off, and through their gradual elevation the whole plant is sometimes raised on what looks like a system of aerial roots.

Again, the twigs are early bent, so that they cross one another, or the stem, in abrupt or zigzag ways, Bamboo-fibres being used to bind them temporarily in place. Thus all growth which does take place is kept within dwarf dimensions, so that the stem, after fifty or one hundred years of life, is often but from an inch and a half to three inches in diameter and about ten times as high. If a bent twig dies it is cut off, and the new one which springs from below it is forced to take its place. This sometimes produces the look of a graft. Frequently a piece of Fern-stem or a bit of tufa or coral is so placed that the main stem bends around it. If all the twisted branches die, new ones are then grafted on the old stock. Conifers bear this sort of treatment much better than dicotyledonous plants, as the tendency of these to throw out side shoots can tire the patience even of Japanese gardeners. For no detail of free growth out of harmony with the forms of the main branches can be allowed. Every smallest twig must scrupulously accommodate itself to the general effect. *Thuyopsis dolabrata*, *Chamaecyparis obtusa*, *Pinus parviflora* and *P. densifolia* are among the conifers most commonly chosen for dwarfing. Some of those exhibited in Paris were nearly 150 years old, and were valued at hundreds of dollars. They tempted the purse of many observers, but I doubt whether any one was rash enough to buy, for it was plain that their value depended on a continuance of the Japanese cultivator's skill—they might as well die at once as live to lose their character through unregulated growth.

What now was the artistic interest of these specimens? Sometimes it was merely the charm that lies in anything quaint, bizarre, grotesque. But often we saw forms so beautiful in their way and so clearly illustrative of one phase of Japanese artistic endeavor that it was a pure delight to study them. Often these little trees were not bizarre and patently deformed, but as fine in their outlines, as grand in their masses, as imposing in their effect, as suggestive of ideas of long existence and vigorous development, as could be the most mighty specimen seen out-of-doors. It needed a little effort to put one's self at the right point of view. But it soon was easy to look at them as the Japanese himself must look—to consider them as miniature representations which the eye knew to be small, but the imagination accepted as large—that is, it was soon easy to look at them as we look at little pictures or at statuettes. If a reproduction of a large form on canvas can satisfy eye and mind, although it measures but a few inches itself, why cannot one be likewise accepted when wrought in the same material as the original? Here was a portrait, so to say, of a great Thuyopsis or Pine, which, in a pot scarce twelve inches across, we could have perpetually at hand not merely to suggest, but actually to show, the beauty of its original. Here in portable shape we had form, color, substance, movement, odor—everything but size; and when we had learned how to look we missed size even less than in one of Barye's tigers or in a miniature of a familiar face. The best of these little trees were not mere curiosities, but true works of art. If simply kept small they would have been the former; but kept small and looking gigantic, they were artistic in intention and result. Of course such an effect could be produced only by the twisting processes employed. Mere retardation of development would not answer. If we could keep a six-year-old White Pine forever of the same size and shape it would never look like a century-old one. It must be forced to take a shape characteristic of maturity. Nor does it matter, I think, whether or not the shape achieved is precisely that of a freely-developed individual of the same species. So long as the dwarfed tree looks as though a freely-grown large one might have assumed this shape, the artistic ideal is achieved.

But still more interesting than these isolated dwarfs were certain arrangements where a number had been grown together. Several creations of this sort had been brought to Paris, but so far as I saw, only one remained in perfect condition. This was exhibited in August at one of the flower shows in the great tent, and may have been noticed there even by visitors who did not penetrate the Japanese section. It consisted of a board about as big as a tea-tray with a raised rim around the back and sides. At the right hand back corner was a thick irregular group of conifers, some eighteen inches in height, massed around a large stone. So carefully had the shape of this stone been chosen and the shape and arrangement of the plants been studied that the effect was precisely the same as though we saw a great precipitous rock surrounded by graceful yet imposing trees of natural size. A lower mass of foliage formed the centre of the background,

and to the left was another higher mass of conifers interspersed with deciduous trees, seen beyond a lofty bridge. The foreground was composed of moss and low grasses broken by taller tufts and by patches of a tiny flowering plant—as I remember, an *Oxalis*—and foreground and background were united by plants of intermediate sizes in the most thoroughly artistic way. The horticultural skill displayed was marvelous; for not only the trees but the grasses and everything else must have been dwarfed to bring them to such fairy-like proportions, an inch counting for a considerable elevation, and the flowers being no bigger than pin-heads, yet each and every plant being in perfect condition, and the general effect luxuriant and rich. It was not a little toy-shop garden—it was a little living picture of a broad landscape of incomparable beauty and grandeur. If one took a moment to get absorbed in the scene before him, he thought no more of dimensions than if he had been looking at painted canvas. What he saw was a shadowy glen where rich green grass was starred with yellow flowers, where coolness and freshness breathed from the air, and in the background great masses of rock and foliage that stirred the imagination as well as refreshed the eye. The marvelous skill of the horticulturist was forgotten in wonder at the power of the artist who could conceive so beautiful a landscape. The way in which foreground, middle distance and background had been contrasted yet harmonized, the grandeur yet softness of the massing, the loveliness of the sky-line, the variety and beauty of the color, all kept in a low, quiet tone with no crude notes—these merits impressed one as in the work of some great painter; and what a painter would have supplied in the way of atmosphere and perspective was added by the modeling and shadowing of Nature herself. Of course the result had not the suggested poetry that we find in a Corot; nor could such a living picture on a board ever give effects of distance or supply the canopy of heaven. But within the limits possible to such work, there seemed nothing that the Japanese artist had not accomplished. As a “realistic” picture of a rocky glen no painter could begin to equal it, for it was as perfect to the tiniest detail as it was in the effect of its largest masses. In short, if on the soil the Japanese landscape-gardener had shown us nothing, here he showed us something in which we could read an account of his larger enterprises.

There was nothing I saw in all the Paris Exhibition that I coveted as I did this exquisite, and, to my eyes, novel work of art. But if it would have been rash to think a single dwarfed tree might survive in European hands, how should one dare to touch this far more complex bit of art-created life? It seemed a pure marvel that it had been brought half way round the world even by those competent to care for it at home.

George Cumming.

Some Old American Country-Seats.—V.

MONTGOMERY PLACE.

JANET LIVINGSTON, a sister of the Chancellor, grew up in the quiet elegance of Clermont, but after her gallant young husband, General Richard Montgomery, was killed at Quebec, she chose and purchased for her home a tract of three hundred acres lying upon the river by the mouth of the Saw Kill and a few miles south of the southern limits of Clermont Manor. Here, with the help of plans which are said to have been sent from Ireland by Montgomery's sister, a Lady Ranelagh, a mansion remarkable for its simple but elegant architecture was built, and the new seat was named Montgomery Place. Here in later years the eminent jurist, Edward Livingston, was wont to retire from the cares of office to enjoy the beauties of nature.

Approaching the estate to-day from Rhinebeck or from Red Hook, the way lies through a charming farming country crossed by numerous lane-like roads and by the one highway which leads to Albany. The approach to the house at Montgomery Place parts from the high-road at right angles, and leads, at first straight, toward the river through an avenue of noble trees of various sorts, planted in rows, yet not in pairs. Indeed, not only is there no precise symmetry, but a giant Locust may here be seen standing opposite a Linden (as in the picture on page 143), or a great Horse-chestnut opposite a Beech; and in one place, where the road is carried on a stone-walled causeway over a little gully, great Willows throw large limbs across the vista. Beyond the rows of trees, on either hand, lie gently undulating pasture-lands, bounded in the distance by woods. Drawing nearer now to the house, the straight avenue ends just as the roadway passes through a tall hedge into the inner park. Here is a wood of fine forest-trees standing well apart, and, as the road curves gently to the right between the trees, a little valley on the left begins to fall away

quite rapidly toward the Hudson. The sides of this valley are richly wooded, and serve to frame a first glimpse of the river, where it is disclosed by the broadening of the valley's mouth. As the road swings still farther to the right, the house comes into view ahead, and branch roads lead on the left to the stable, and to the kitchen yard, which is concealed by shrubbery and by being sunk to the basement level at the southern end of the house. The main road ends with an ample turn, placed symmetrically before the semi-circular portico which marks the entrance. The guest of the house who turns here looks eastward back toward the Albany road across a gently rising lawn bounded, on one hand, by the same dense wood which he before saw limiting the northern pasture, and, on the other, by the more open groves through which he has just traveled. Formerly this sheltered open ground contained the flower-garden and an elaborate conservatory; and, on the gentle rise behind this structure, a considerable arboretum once existed, where now only a few scattered specimens are to be seen; but from the point of view of design and general effect the substitution of the existing simple but well framed lawn in place of the old garden and conservatory is by no means to be regretted. The entrance front of the house as it now appears, when viewed from the site of the conservatory, may be seen in the picture on page 142; but though the building and the great Locusts near the porch are well shown, the picture gives no hint of the blue distance of hills and mountains which in reality appears through the tree-trunks just north of the house.

If, tempted by this glimpse of distance, the visitor turns the corner of the building and steps into the round-arched pavilion which is attached to the north side of the house, the whole broad panorama of the river and the Catskills is spread before him to the westward; but even here the wide prospect is broken into scenes and framed by the solid piers and arches of the pavilion itself, and by the trunks and branches of great trees, chiefly Locusts, standing on the brink of the irregular grassy slope which falls steeply to a narrow wood on the bluff at the river's edge. “To attempt to describe the scenery which bewitches the eye as it wanders over the wide expanse to the west from this pavilion would be an idle effort,” wrote Mr. Downing in 1847. “As a foreground, imagine a large lawn waving in undulations of soft verdure, varied with fine groups, and margined with rich belts of foliage. Its base is washed by the river, which is here a broad sheet of water, lying like a long lake beneath the eye. . . . On the opposite shores, more than a mile distant, is seen a rich mingling of woods and corn-fields. But the crowning glory of the landscape is the background of mountains. The Kaatskills, as seen from this part of the Hudson, are, it seems to us, more beautiful than any mountain scenery in the Middle States. It is not merely that their outline is bold, and that the summit of Roundtop, rising three thousand feet above the surrounding country, gives an air of more grandeur than is usually seen even in the Highlands; but it is the color which renders the Kaatskills so captivating a feature in the landscape here. . . . Morning and noon the shade only varies from softer to deeper blue. But the hour of sunset is the magical time for the fantasies of the color-genii of these mountains. Seen at this period, from the terrace of the pavilion of Montgomery Place, the eye is filled with wonder at the various dyes that bathe the receding hills—the most distant of which are twenty or thirty miles away. . . . It is a spectacle of rare beauty, and he who loves tones of color, soft and dreamy as one of the mystical airs of a German maestro, should see the sunset fade into twilight from the seats on this part of the Hudson.”

Mr. Downing did well to sing the praises of the Catskill sunsets, and he might have added that this favored pavilion of Montgomery Place spreads its prospects before the visitor to the delightful accompaniment of the music of waterfalls sounding from the depths of the wood near by. Upon entering this wood it is seen to occupy a large and long valley curiously broken into lesser ravines and hollows. Numerous paths lead through the dark shadows of the wood to all the finest parts and to the falls—one of them forty feet high—by which the Saw Kill plunges down to join the Hudson. Here are wildness and extreme picturesqueness in sharp contrast with the stately breadth and quietness of the lawns and groves about the house and the majestic panorama of the river. Well may Mr. Downing have called Montgomery Place second to no seat in America for its combinations of attractions; and it may be added that its makers and owners—all of them Livingstons, or close connections of the family—have been second to none in the taste and skill which took advantage of glorious opportunities and in the care which has preserved the essential features of the original design until this day.

Charles Eliot.

Vegetation in Southern Alabama.

THE first frost of the last winter appeared here on the 26th of November, and two lighter ones followed on the first two days of December. These chilly mornings scorched the foliage of tender tropical plants which were yet unhooused, but the vitality of the stems remained unimpaired. The Cestrums, Brugmansias, Hibiscus, Lantanas and Abutilons soon recovered and continued to bloom. Bananas, Caladiums, Hedychiums and Cannas quickly threw out new leaves, and now, on the first of March, are clothed with fresh young foliage. Aloes, Dracænas, tender Yuccas, Palms, *Cycas revoluta* and the various Cactuses are thriving luxuriantly in the open air, while Geraniums, Begonias, Amaryllis and a few tender Amazon Lilies (*Eucharis Amazonica*) have been flowering all winter long. Those exotic woody plants regarded as hardy here never showed greater luxuriance. The Camellias produced a remarkably abundant crop of flowers. The hybrid Azaleas have been blooming now for nearly three months. Chinese Magnolias, Forsythias, Siberian Honeysuckles, *Photinia serrata*, Laurestinus and Daphne, with the Dutch bulbs, began to bloom on the first week of the new year and were quickly succeeded by *Magnolia fuscata*, Wistaria, and a profusion of Tea Roses, like Marechal Neil, Lamarck, Malmaison, Cloth of Gold, Sombreuil, and that everlasting bloomer, Archduke Charles, not to speak of the variety of herbaceous annuals and perennials which are now more than five weeks in advance of ordinary seasons.

In the last half of February car loads of Cabbages of the finest quality were shipped to northern markets. Irish Potatoes are now eight inches above ground, and the earliest varieties already show signs of bloom, and Strawberries are abundant. No one has ever seen the Japanese Medlars (*Eriobotrya Japonica*) bending under heavier loads of fruit, and no object could be more attractive to the eye than these trees now are with their golden fruits nestling among the dark green foliage. This tree is a prime favorite on the Gulf Coast, where, in warm, light loam, it finds a suitable soil and proves perfectly hardy. Seedlings spring up wherever the seed is accidentally dropped in raw soil, and such volunteers grow vigorously without cultivation and can be transplanted at almost any time of the year. The fragrant flowers of this tree open late in October and last nearly a month, and it is only in winters when there are long periods of cold, wet weather that it fails to produce fruit. The juice of the Medlar has a mild acid taste and an agreeable flavor, but it is not regarded as suitable for transportation to distant markets. It is my experience, however, that clusters freed from all defective fruit and packed in sawdust will carry without injury.

For the first time in ten years the Sweet Orange gives promise by its profusion of bloom of a full crop. The trees now coming into bearing are mainly those which sprouted from trees cut down by the freezing weather in the winter of 1880-'81. During the decade preceding the one just passed the orange crop was looked upon as the most remunerative one which could be grown in localities suitable for it. Some groves of small extent, on the shores of Mobile Bay, yielded an income of many thousand dollars a year, and therefore the cultivation of the Orange up to the disastrous winter was actively carried on. The fruit produced here, the Creole Orange of Louisiana and Mississippi Sound, leaves little to be desired in quality. Large, thin skinned, fair, finely colored, rich in flavor, with tender flesh and abundant juice which blends acidity with sweetness, all these qualities render it agreeable to taste, and superior to the fruit from tropical countries. According to the testimony of old settlers the cultivation of the Orange must have been more successfully carried on by the generation preceding the present than it now is. The reason, perhaps, is that years of destructive cold appeared at longer intervals. A frost in 1852 killed the orchards, as it did in 1880. The plantations that started anew from sprouts received a check during the winter of 1884, from which the trees mostly recovered and yielded crops up to 1880. It is to be hoped that since these freezing periods are so rare some means may be devised for protecting the orchards on these special occasions, now that we can be forewarned of the advance of cold waves by the Signal Office.

Turning to the woodlands, we find the deciduous trees and those with half persistent foliage, like the entire leaved Oaks, rapidly unfolding their leaves. The Cuban Pine has already shed its pollen. The Mock Orange (*Prunus Caroliniana*) has also bloomed; and so has the Ti-Ti (*Cliftonia ligustrina*). The Dogwood, Plums and Sparkle-berries (*Vaccinium arboreum*), the American Olive, Sweet Illicium and Haws are opening their flowers. The Mulberry and May Haw (*Crataegus*

astivalis) begin to ripen their fruits. The Loblolly Pine and Long Leaved Pine are unfolding their catkins weeks in advance of ordinary seasons. The Cherokee Rose is brightening up the wood borders and hedgerows with its flowers, while the yellow Jessamine, the Woodbine, the Cross Vine, the China-tree (*Melia azedarach*) and the Pomegranate are all in full bloom.

Foreign Correspondence.

London Letter.

DISEASE OF ORCHIDS.—Some alarm has arisen amongst Orchid growers here in consequence of the appearance amongst Cattleyas of a very virulent and invariably fatal disease, the exact nature of which has not yet been determined. Some microscopists declare that there are clear evidences that the disease is caused by a Peronospora; others, on the contrary, are equally certain that the disease is not due to any fungus whatever, although a fungus may easily follow on the heels of the disease and be mistaken for the cause. About a year and a half ago a perfectly healthy plant of the autumn-flowering *Cattleya labiata* at Kew suddenly turned black and pulpy, as if it had been boiled. We were unable to account for this; no other Cattleya was attacked, nor have any been lost in the same way since. Examples of the same disease on *C. Hardyana*, *C. gigas*, *C. Dowiana* and *C. labiata* have been received at Kew within the last twelve months from expert cultivators, who were puzzled by the sudden collapse of plants which, until the disease appeared, were in perfect health. The whole of the material is in the hands of Professor Marshall Ward, whose report is anxiously looked forward to by hundreds, who are naturally dismayed by the ravages of this disease. Meanwhile it is interesting to note that an eminent fungologist at Kew experimented with the disease by inoculating a healthy plant and smearing another plant, also healthy, with some of the diseased tissue, the result being that whilst the inoculated plant turned black and rotted in three days, that which had been smeared remained apparently uninfected. The result of this experiment makes the disease, if not fungoid, still more mysterious. In one case reported to the Kew authorities there were two distinct plants of *C. gigas* growing side by side in the same pot, or what is known as a "made-up specimen," and whilst one of these was killed by the disease, the other remained uninjured, and is alive still. This disease must not be confounded with ordinary "spot," to which all Orchids are liable under certain conditions. At the last meeting of the Royal Horticultural Society specimens of Orchids affected with the first described malady were exhibited by a gardener, who was "anxious to know if there was any remedy, as he feared his collection was in danger of being destroyed." I do not believe there is any occasion for so much alarm, more especially after hearing from Professor Ward that the disease is not caused by a fungus.

LONDON FOGS.—Some time ago I mentioned the difficulties experienced by cultivators in the neighborhood of London owing to the frequency and poisonous nature of fogs in winter. The subject has since been taken up by the Royal Horticultural Society, with the result that the evidence collected shows the matter to be of so much importance that a government grant of £100 has been applied for to facilitate the investigation of the subject by chemists and physiologists. The present winter has been comparatively free from the black, or rather copper-colored, fogs, which during last winter did frightful injury to in-door plants of all kinds. We have a Smoke-abatement Society in London, but it does not appear to have any influence in the reduction of the smoke nuisance.

WEATHER.—We are experiencing now much colder weather than we had all through January. This morning, the 28th of February, the thermometer registered eight degrees of frost, with a cold east wind and snow falling. We have reason to feel grateful for this timely check to vegetation, which a month ago was so forward as to cause alarm for the safety of fruit and out-door plants generally. Notwithstanding the cold, the lawns have lately been bright with thousands of yellow Crocuses, Snowdrops, Winter Aconites and blue Squills. The effect produced at this time of year by these plants when set in thousands on sloping lawns is particularly good. Apparently they become established, for this is their fourth year on the lawns at Kew.

MOTH-TRAPS.—At a recent meeting of the British Fruit Growers' Association, Mr. T. W. Beach, who grows fruit very largely and is one of the principal jam-manufacturers in England, exhibited an excellent contrivance for trapping moths, etc., which infest fruit-trees. The trap is simply an

ordinary petroleum lamp, furnished with an extremely wide shade, the under surface of which is white, and covered with a mixture of grease and tar or any sticky substance. The moths are attracted by the light, and in flying about it they come in contact with and are held by the adhesive mixture. This simple but first-rate contrivance has been tried in several orchards with much success. To catch the enemy before it has sown the seeds of mischief is certainly a much more sensible way than to fight with the mischief itself.

TRADE-UNIONISM FOR GARDENERS.—The improved position of the followers of many trades and professions in England which has resulted from combination, has set gardeners to thinking whether something of the same kind could not be done by a union of a similar kind amongst themselves. The scheme propounded by the first to move in this matter is, briefly stated, an association for all professional gardeners; a registry of places and men; the boycotting of all who are not members of the association; the issue of certificates to all qualified gardeners, and the limitation of apprentices with a view to relieving the present very congested condition of the horticultural labor market. Whilst it is felt that, considering the nature of the training a man must undergo before he becomes a competent gardener, he is, as a rule, very badly paid, it is clear that so long as there are twice as many men as there are situations for them, there is small chance of a rise in gardeners' wages. There is small prospect, therefore, that the movement will prove very helpful. England is admittedly the best training ground for horticulture, and we are committed to free trade in labor as well as in everything else. Combination or a "strike" amongst gardeners would probably result in a loss to themselves, as horticulture is very much of a luxury, and a man cannot be compelled to pay more than he chooses for his luxuries. With the nurserymen it is different, and consequently nurserymen pay their permanent staff well, as they are bound to do. Meanwhile it is a curious commentary on the complaints of the gentleman's gardener that whilst he cannot command satisfactory wages, employers are at their wits' end to find competent men. Only this week I have been informed of three first-rate situations for Orchid-growers for which suitable men were not forthcoming.

London.

W. Watson.

Berlin Letter.

GERMANY is the land of societies, and it is no wonder, therefore, that at the capital of the Empire there are not only one or two, but half a dozen horticultural societies. The oldest and most important one of these is the Society for the Advancement of Horticulture in the Royal Prussian States. Its members are gardeners, amateurs and many botanists. It is the society which is now attracting general attention, from the fact that under its direction is to be held the great International Horticultural Fair, of which I wrote you in a former letter, and in which the decorative features of horticulture are to have the leading place.

Another old society, which is held in high esteem, is the Berlin Horticultural Society; its members are mainly nurserymen in the vicinity of the city. Then there are a Gardeners' Society, a Society of Commercial Florists, a Society of Fruit-growers, and a Society of Graduates of the Pomological Institute at Proskau. The gardeners of Berlin make a great deal of society life, but the activity of this life is confined mainly to the winter months, because in summer, work, in most of the nurseries, begins at four or five o'clock in the morning and ends at eight or nine in the evening. The number of nurseries where the work begins at six or ends as early as seven is very small. It is little wonder, then, that society life drags in the summer season.

The Society for the Advancement of Horticulture has monthly meetings, at which prizes are offered for special plants and discussions are held on subjects connected with them. Prizes were offered for groups of ten Amaryllis at the January meeting. Of three competitors, the head-gardener of the famous garden of the late Mr. Borsig gained the first prize, which was a large silver medal. His specimens were so vigorous, the flowers were so large and the colors so brilliant that they might well compete with the best English plants. The cultivator said that pot-culture was best for these bulbs. He transplants them but once during their period of vegetation, and thus gets strong bulbs, each of which bears two scapes with a pair of flowers. The second competitor showed seedling Amaryllis, and his practice is to plant the young bulbs out, whilst strong bulbs are cultivated in pots, plunged in warm soil four inches below the surface. Then the roots grow over the rim of the pot, and no further transplanting is needed. A

variety of *Clematis patens*, called Vesta and trained in balloon form, was exhibited at the same meeting. This beautiful white flowering plant was greatly praised by its exhibitor for winter bloom and cut flowers. Another good winter blooming plant shown was the new *Iris Bornmuelleri*, with yellow flowers. It was sent to the exhibitor by a collector in Persia, and it flowered in a cold frame in the middle of January. *Anemone blanda* was also shown and highly commended, because it had flowered in the open air in the last week of January along with Christmas Roses and *Eranthis hyemalis*. This, indeed, may be our earliest spring flower in the open air. Eranthis is flowering freely in the botanical gardens here, although the temperature fell below zero last week.

Specimens of *Lilium auratum* in flower attracted much attention. The bulbs are placed in an ice-cellar immediately on their receipt in autumn, where they are kept until needed for forcing. They are at once brought into a house with a temperature of from fifty-nine to sixty-four degrees Fahrenheit, when good sized bulbs will show four or five flowers in four weeks. The flowers are highly appreciated here in the winter months, and they are quite often seen in the flower-shops this winter. It has been supposed that they were imported from the Riviera like Roses, but this exhibitor said that other florists as well as himself raised many of them here.

The beautiful *Tulipa Greigi*, from Turkistan, is another flower which had been forced for exhibition. It began to bloom about the 20th of January and lasted for a long time. It was remarked, however, that the colors of the flower were not as brilliant nor the marking of the leaves as decided as when they were grown in the open air. It was stated that this Tulip, unlike most others, does not thrive well in a sandy soil, but needs a strong one, which does not thoroughly dry out in the summer-time. Deep planting is also necessary for its best development. One member stated that Tulips and Lilies gave the best seed when the scapes are cut and put in water to ripen. Under these circumstances the reserved nutrition is used for the development of seeds, while in the other case, where the scape remains on the plant, the reserved nutrition is carried downward to be stored in bulb. The question is one of sufficient interest to demand investigation, as was another made at this meeting, to the effect that in England some growers of Chrysanthemum-seed cut off the flowers and place them in water, thinking that in this way they get better seed.

Berlin.

Udo Dammer.

Cultural Department.

Notes on Strawberry Culture.

THIS year's fruit catalogues contain florid descriptions of many new and apparently desirable varieties of Strawberries, and it is quite perplexing to find that each one of these varieties is claimed to be of better quality than any other one. For many years I have been buying "the very finest of Strawberries." I have tested about twenty-five sorts, with a hope of reaching some day the climax of perfection, yet I sometimes doubt whether any Strawberry has yet been found which is better than the old Wilson's Seedling.

However, the Wilson seems to be declining in southern New Jersey, and I have now supplanted it with a sort which, with me, does better, known as the Pearl. This variety, as it grows here, is remarkably well rooted, of vigorous habit and of as good quality as any I have tried.

The quality of a Strawberry depends much on the soil in which it is grown, how the plant is manured and the weather under which the fruit ripens. Varieties which are excellent when grown under conditions favoring them, are comparatively worthless when these conditions fail. It is generally thought that the Strawberry requires high culture and fertilization with stable manure; yet this treatment will harm the quality of any variety of Strawberries. I have found Strawberries to do best on a fairly fertile soil, and fed with potash and lime, with no nitrogenous manures. If the plant be richly fed with nitrogen its fruit will be soft, flavorless and prone to decay. If treated with potash and lime it will be sweet and durable.

I once had a patch of Strawberries on new land which had not been manured. In the winter I top-dressed the field liberally with water-slaked shell-lime, spreading this on the rows so as almost to cover and hide the plants. A neighbor had a Strawberry-patch of like age and of the same variety—the Wilson. His land was freely fertilized with stable manure. One hot day I picked 400 quarts of strawberries and shipped them to Boston. On the same day my neighbor did likewise. My fruit reached Boston in good order and sold for a high price.

My neighbor's fruit reached there the same day, soft and unsalable. It did not bring enough to pay the freight. The difference in these berries was due simply to the differing effect of the stable manure and the lime. The same day that I sent these berries to Boston I sent a thirty-two-quart crate of them to friends in Kittery, Maine. This crate was on the road a day longer. The berries in it were selected, the largest and ripest, mostly dead ripe, yet these berries arrived in perfectly good condition, and my friends wrote that they were the finest they had seen.

The Wilson Strawberry, grown with potash and lime, and left to become dead ripe, is hard to beat, either for market or for the table; but nitrogenous manure will spoil it. It may increase the size of the berry, but it will be at the expense of sweetness and solidity. There need be no fear that liming the Strawberry-plant will injure it. Living vegetation is not harmed by the contact of water-slaked lime, though it will

tion. Not a berry ripened, and in the course of two weeks one could hardly find a green leaf in the whole acre. The plants died utterly.

Such complete destruction by this fungus is unusual; commonly only the leaves perish, and a new growth starts from the root-crown. This growth will in its turn become diseased from the fungus-spores which pervade the tissues they have destroyed. In these the spores of the fungus hibernate, and hatch with return of warmth and moisture in the spring.

I do not know whether lime will destroy the hibernating germs of this fungus, but from sundry experiences in its application I am disposed to think it will. However, it is known that lime prevents the germination of the summer spores of blight by which the disease is most rapidly spread. It is well to give the Strawberry-plants a liberal coat of lime in winter or early spring, and repeated lighter doses of dry lime before and after blossoming until the fruit is about one-third grown,

Montgomery Place: Entrance Front.—See page 139.

help decompose dead vegetable matter. I have covered Strawberry-plants two inches deep with slaked lime, and seen the plants grow up through it.

The Strawberry blight (*Sphaerella Fragariae*) may be prevented by a free and timely use of lime. All our varieties are more or less liable to harm from this fungus, which manifests itself in small purple or red spots on the leaf. As these spots increase in size they become a reddish brown, with a white spot in the centre. The leaves badly diseased turn brown, die and shrivel. This will be noticed especially where the fungus has attacked the petiole. Then the leaf will soon wither, though it may not be spotted. The fungus often invades the fruit-stems or the calyx. When this happens the growth of the berry is stopped. Moist and poorly drained soils and damp and "muggy" weather favor its rapid development. Years ago I had an acre of Crescents, carrying a heavy crop. When the berries were about one-third grown the field was struck by this blight, which swept over it like a conflagra-

tion. when the crop will be reasonably safe and the liming should cease or there will be risk of disfiguring the fruit should there be no rain to wash off the lime. The lighter applications of lime may be conveniently made with a bellows. It is only requisite to make a slight, but thorough, distribution of the dry powder over the entire surface of the plant. If the lime be on the leaf when the fungus germs alight on it they can do no harm. If the germs reach the leaf before the lime does, they will germinate and enter the tissues, and then the lime cannot affect them. The treatment of Strawberry blight can be preventive only.

Spraying the plants with a solution of hyposulphite of soda, one pound to ten gallons of water, is also preventive of blight. So is a solution of sulphide of potassium, one pound to forty gallons of water. The various formulated solutions of copper sulphate or carbonate are also preventive, but it must be remembered that all these chemicals are useful only as preventives of disease. The defense must interpose before the

attack arrives. Another preventive of blight is to burn over the berry patch. This destroys the seed of the infection. But the weather may prevent the doing of this at the proper time. In place of fire I use sulphuric acid, which acts like liquid fire. Spraying with a solution of one quart of the acid in twenty gallons of water will completely burn the vegetation and the fungus, and this can be done when convenient, regardless of the weather. I thus burned some rows of blight-infected plants in June, 1889. The new growth from the root-crowns remains healthy. I shall, however, again spray them with this burning fluid before the growth starts this spring, after which I expect to see no more of *Sphaerella Fragariæ* on these plants this season. This treatment is not expensive. The material will cost about fifty cents, and one may spray an acre of plants in an hour and a half.

mond toothed cultivator, then once hoed, some twenty plants reset, and afterward twice cultivated, one way only, leaving the plants in matted rows, which are matted enough. Three feet apart in a row is close enough to plant the Pearl, which is a strong runner. Even at four feet the rows will fill up with plants.

In December, 1889, this acre of Pearls was top dressed with two tons of Canada unleached ashes and a hundred bushels of lime. Next June I expect to harvest from it a healthy crop of berries which will bear transport to Canada.

When this crop is off the Strawberry sod will be plowed under and planted on the first of July to white Peach-blow Potatoes, fertilized with a ton per acre of "potato manure." Next year the ground may be again planted with Strawberries, which will be again manured with unleached ashes and lime.

Vineland, N. J.

A. W. Pearson.

Montgomery Place: An Avenue.—See page 139.

It is well to avoid damage from this blight by restricting Strawberry-plants to one crop. Make new plantations yearly. An acre of Strawberries may be planted almost as readily as an acre of corn. With ground in good order in April, mark it off three feet each way. Have the plants ready with roots straightened out and puddled. Use a broad bitted turving hoe. At the intersections of the rows strike this hoe into the soil at an angle of say forty-five degrees. Depress the hoe handle. This will open a gap in the soil beneath its blade. A man with basket of plants takes one of these, shakes its roots apart, and sticks them into the opening made by the hoe, so the crown of plant will be level with surface of the ground. The hoe is then withdrawn, the gap it made closes on the roots, the man with the hoe sets his foot on the plant, firming it in the soil, and proceeds to the next hill.

This seems a rough operation, but last April two men thus set an acre of five thousand plants in a half day. Two weeks after setting the rows were cultivated both ways with a dia-

Winter Notes on Trees and Shrubs.

THE general appearance of the stems and branches of deciduous trees and shrubs in our woods and gardens in winter is often of a very varied character and sometimes strikingly beautiful. The many pendulous, pyramidal and other so-called varieties of trees, which have been diligently propagated by nurserymen, are not more interesting than the diversity of forms to be met with in the fields, or more rarely in our open native woods. But when we regard the beautiful harmonies and contrasts of color of trunks and branches, occasionally produced in nature in what seems a haphazard way, the wonder is that effects of this kind have not been more extensively attempted in ornamental planting. The form of the trunk and the position and angle assumed by the bare branches of trees do not appeal to the eye of most people as do the colors of the bark, which, in many cases, cannot fail to attract the attention of even the least observing.

This is shown by the prominence given in many small gardens to the white-stemmed Birches, which Coleridge, referring to the European species, called the

——— "most beautiful
Of forest trees, the Lady of the woods."

In a great proportion of the species of our large growing trees, such as the Oaks, Ashes, Elms and Maples, the old and dead bark usually has a more or less brown or sombre gray appearance, except where vitality and color is given by mosses, lichens or other low forms of vegetable life upon it. The older parts of some species of Poplar are light in color; other trees, like some of the Beeches, have uniformly smooth trunks, and still others have the curiously blotched appearance of our Buttonwood-tree. A very few trees have stems whose bark retains some striking peculiarity of color after it has become inert and apparently of no vital use to the tree, but nearly all show green or some brighter color in the younger branches.

Of the White Birches, already referred to, a common one in New England gardens is the native *Betula populifolia*, which never becomes a wide-spreading tree or more than thirty or forty feet high. In the poor soils in which it is most often found it usually occurs in thickets and shrub-like clumps. Planted against a dark or evergreen background it is certainly conspicuous, with its white stems and dark green, slender branchlets. Of weeping and other forms of White Birches propagated by nurserymen, those of the European species (*B. alba*) are the most common, and, it may be added, generally the most interesting and graceful.

A much more beautiful tree in every respect is the Canoe Birch (*B. papyrifera*), and it is perhaps never so strikingly attractive as when its large, shining, pure white trunk is seen mixed with the dark hued stems of other trees in its native woods. Where it has room to develop it sometimes becomes a beautiful, broad-spreading tree whose coppery bronze colored branchlets form a curious contrast with the dazzling whiteness of the older bark. Few deciduous trees have a greater charm than this when leafless, but, like its other white stemmed congeners, its beauty is best shown by contrast. One other species is conspicuous in the woods in winter, the Yellow Birch (*B. lutea*) having its trunk covered with loose, thin, curling flakes of silvery or yellow bark. The charm of this is lost when the tree is growing in exposed situations, as the bark then becomes dull-colored or weather-beaten.

Next to the Birches some of the Willows attract attention by the yellow, red or bright green of their branches, the colors of which deepen with the coming of mild days in late winter and early spring. A few shrubby species are particularly showy, both by the color of their bark and the half developed catkins which they bear. One of the most pleasing, as well as one of the most rare, native species is *Salix balsamifera*, of the White Mountains, and further northward, which has clean, glossy russet, yellowish brown branches, and reddish buds.

Among all our hardy trees, there are none which in color possess more delicately pretty stems and branches than the small Striped Maple (*Acer Pennsylvanicum*) of our northern woods. Without having the glaring prominence of the White Birch, the beautiful striated bluish white and green or brown marking of the smooth bark of this tree at all seasons makes it a desirable one for any lawn. Good specimens are rarely seen in cultivation, but when well grown they are trim and ornamental little trees. Some other Maples may have more brightly colored branchlets than this species, but they lack the peculiar charm of its stem. The same observation applies to the Lindens, some of the propagated varieties or forms of which are noted for the golden yellow, bright red or other colors of their twigs, while the bark of all the older parts becomes gray. The showy colors of the twigs of tall, upright growing trees, however, do not usually attract the eye as do those of dwarf and spreading habit, or shrubs.

Of the latter, a few species of Dogwood are certainly among the most conspicuous, and are usually planted for the color of their stems, and, in popular esteem, they occupy a place among the shrubs equal to that of the White Birch among the trees. The white-fruited Dogwood (*Cornus alba*), of Siberia, is the most conspicuous as well as the most generally cultivated, both in this country and Europe. The deep, blood-red color of its stems and branches, which becomes richer as spring approaches, makes a brilliant and striking show at any time, but is naturally most prominent when the ground is covered with snow. There are several horticultural forms known to nurserymen under the names of *Sibirica*, *Atrosanguinea*, etc., having stems of varying shades of scarlet or red, besides those with peculiarities of foliage; and, unfortunately, in many

catalogues the species is given as *Cornus sanguinea*, a name properly belonging to a larger growing European species having little of interest in the color of its bark, which becomes gray when old. Next to the Siberian species our native *Cornus stolonifera* possesses the bright scarlet twiggled quality in a high degree; and the branches of the Silky Cornel (*C. sericea*) have a more or less purplish hue. When judiciously planted, a selection of these and some of the dwarf Willows, besides several other shrubs with peculiar color of bark, would do much to brighten our winter landscapes. J. G. F.

Arnold Arboretum.

Cœlogyne cristata.

THERE are over one hundred species of *Cœlogyne* known to botanists, but not one of them can compare in popularity with the subject of the present note. Indeed, *Cœlogyne cristata* must be regarded not only as the finest representative of the genus to which it belongs, but also as one of the best known and most generally cultivated Orchids. Not only does it take precedence of all other *Cœlogyne*s in these respects, but it is also interesting as being the first species upon which Dr. Lindley established the genus in 1825. Its appearance in cultivation dates from the year 1837, when it was successfully introduced from the mountains of Nepal by Dr. Wallich. It is a native of this and the surrounding regions of north-eastern India, where it has been found growing on rocks and trunks of trees at elevations varying from 5,000 to 8,000 feet above sea level. In 1841 it was first publicly exhibited by Mr. Barker, of Birmingham, to whom was awarded a silver Knightian medal at one of the spring meetings of the Horticultural Society of London.

The typical *C. cristata* is recognized by its globose or oblong pseudo-bulbs, which vary in size from a small green-gage to a large hen-egg. They are produced in great masses at intervals of one, two and three inches on a strong rhizome thickly covered with imbricating, brownish scales. On the summit are borne two oblong-lanceolate leaves, nine to twelve inches long, the upper surface of which is deep green, the under surface being much paler. The pendulous or arching scapes are produced from the base, and are clothed with sheathing bracts. Each scape usually bears from five to eight flowers, measuring three to four inches across, and of the purest white color with the exception of an orange-yellow stain on the disc of the lip. The oblong sepals and petals are undulate on the margins and more or less twisted at the tips. The lip is three-lobed, with rows of erect, comb-like fringes on the orange-yellow disc. The second and fourth of these rows are much longer than the others, and form a solid, erect and more or less toothed plate in front. The column is pure white and slender, furnished on each side with a thin wing, which becomes wider toward the apex, where it forms a kind of shelter to the bluntly beaked anther. The front lobe, as in nearly all *Cœlogyne*s, has two sunken, converging lines which almost form a triangle in the centre.

There are a few distinct varieties of this species known, chief among them being *Alba* or *Hololeuca*, which differs from the type in having absolutely pure white flowers without a stain of yellow. It usually blooms a month or six weeks later than the type. The variety *Citrina*, perhaps better known as *Lemoniana*, is characterized by having a delicate wash of lemon color on the lip instead of orange-yellow. The *Chatsworth* variety is noted for its strong habit, having very large pseudo-bulbs. The flowers are similar to those of the type in color, but are larger in size and have the sepals and petals less twisted. *St. Albans* variety, or *Maxima*, as it is often called, may be said to be even more robust than the *Chatsworth* variety, and to have somewhat larger flowers, with much less twisted sepals and petals and a broader lip.

Cœlogyne cristata is best grown in large, shallow pans, furnished with holes underneath and at the sides. Three parts of their depth should be filled with clean crocks, over which must be placed a layer of rough, fibrous peat and moss. Above this comes the mixture of rich, fibrous peat, by itself or mixed with a little loam, in which the plants will freely grow. During the spring and summer months liberal supplies of water may be given as the plants are growing, but the quantity must be diminished as the bulbs are getting mature. Then the flower-spikes begin to push forth, but it is not until nearly two or three months afterward that the handsome blooms expand. During the season of flowering—that is, in December, January and part of February—very little water need be given until the growths begin to appear again, which is usually about March. If specimen plants are required, repotting will be unnecessary until two or three years have elapsed, by which time the pseudo-bulbs will have become

much crowded, and will require thinning out. The winter temperature for this species should vary from fifty-five to sixty-five degrees, Fahr., and a few degrees more in the summer.

St. Albans, Eng.

John Weathers.

The Spring Garden.

THE earlier flowers are usually most uncertain in their time of blooming, but this season they have carried their vagaries to the extreme, and began to bloom in the first days of the new year. In planting a garden one usually has an eye to effective combinations and harmonies, and while in the early garden these pleasant pictures are often slightly disturbed because some plant fails to contribute its color at the anticipated time, I have never before known such a revolutionary change in the schedule. Snowdrops in a southern border were showing color on the first day of the year and were soon after in full flower. Owing to the comparatively low temperature there has been a succession of flowers for quite two months, and, in fact, a few lingering ones were snugly buried under the snow last week. Two months of Snowdrops means much pleasure to a lover of flowers, for those exquisitely lovely flowers, usually the first harbingers of spring, have a purity, delicacy and freshness all their own. Elwes' Snowdrop (*Galanthus Elwesi*) is the most satisfactory variety for the border, since it is very much larger in all its parts than *G. nivalis*, and slightly earlier. More conspicuous it is, too, though not at all coarse. The buds of *G. Elwesi* are comparatively shorter and more round than the elegant pointed buds of *G. nivalis*. This is an Asia Minor variety, originally found by Mr. H. J. Elwes, and, as it has become plentiful, it should have a place in every garden. No garden ever had an overstock of Snowdrops. Plant them thickly and let them alone to make nice clumps. Like many of the small spring flowers, they require time to become established in masses and effective. For the collector of curiosities there is a number of varieties of *Galanthus* (perhaps a dozen or so), differing more or less widely, but as many of them are so nearly alike that experts seem to have difficulty in their separation, the difference in some cases must be very fanciful. The great curiosity in the family is *Galanthus nivalis Octobrensis*, which, as its name implies, blooms in October. This variety is excessively rare.

Viewing with the Snowdrops in earliness of bloom, a little colony of *Anemone blanda* has given me great pleasure and is still showing its bright flowers with foils of charming foliage—"each spray," a friend says, "a bouquet of itself." This *Anemone* is also from Asia Minor, and a true winter-flower, by which I understand one that will pass unharmed when in bloom through the severest weather, a distinction I was trying to make against the Hellebores not long ago in these columns. Collected forms of *A. blanda* range in color from deep blue to white. They bloom almost as soon as they appear above ground, and they appear as soon as the surface soil is free from frost. The foliage is deeply cut and has a bronzy hue which is very attractive. *Anemones* are not usually happy in my garden, but this species bids fair to be as satisfactory as it is beautiful. Without doubt it should be counted a first-rate addition to the earliest blooming plants. A cheerful plant is the old Winter Aconite (*Eranthis hyemalis*), with its bright yellow flowers within their green collar. These plants gave a flush of color in February which was all too short. They are somewhat slow to become established, but are very hardy, very dwarf, and good things to tuck into the front of a crowded border, where they will be undisturbed.

Elizabeth, N. J.

J. N. Gerard.

Kohl Rabi.

THIS is a vegetable of peculiar habit of growth and a curiosity to many, as I have found when offering it for sale. The leaf of the plant resembles the leaf of the Cabbage, and it grows out of the sides and centre of an enlarged root that lies on the surface of the ground, a round mass varying in size and usually three inches in diameter. The root has the texture of a turnip, with the flavor of a cabbage. The early White Vienna is well and favorably known as a tender and rapid-growing variety; but the red or purple color is only a superficial difference, and the flesh of all varieties is nearly white, and when not overgrown very tender. When old the fibre of the root extends upwards, first on the outside and then through the heart of the vegetable; a thick rind taken off at first will remove all the fibre, but when the root is filled it is useless.

The best practice is to plant seed in succession for use, because after the bulb has begun to form the period in which it is edible is comparatively short. It is very easy to grow, and

is less affected by the attacks of the cabbage-worm than other members of the Cabbage family. The seeds for the first crop should be planted about the first week in March and treated in all respects like Cabbage, setting the plants in the open ground as soon as Cabbages can be set. The growth in rich land will be rapid, and a second planting a month later will make a succession. For fall use, sow in open ground early in July. My practice is to transplant, but this is not necessary, as the plants can be thinned where they grow to about six inches apart, having the rows two feet apart. They bear transplanting and extremes of heat and cold or drought well. In fall the unused plants are taken up, and, after the leaves are cut off, are set with the root in earth in a cellar, where they will keep well into the spring months, and be as good as when harvested.

To prepare for the table a common method is to pare, cut in cubes of about an inch square, boil till tender, and then serve with drawn butter.

W. H. Bull.

Symphoricarpos racemosus, var. pauciflorus.—This dwarf variety of the common Snowberry in its natural home is usually a low, diffusely branched little shrub growing on rocky banks, sometimes in the sunlight, but oftener in the shade or partly shaded situations. The flowers and fruit are neither numerous nor conspicuous, but the dense light green foliage, which seems to retain its freshness throughout the season, is quite pretty, and the plant seems to thrive in a thin and poor soil when most others would not. In its native home, where the soil is very thin, it is often no more than six inches high; but these same dwarf plants attain a height of fifteen to twenty inches in one season when transplanted into the nursery. It thrives well under cultivation, producing larger foliage and a longer growth of branches. *Shepherdia Canadensis* is another shrub more difficult to transplant than the dwarf Snowberry, but frequently growing with it. It is never so abundant, but it has many valuable qualities. The usual height of this shrub is about four feet. The flowers are dioecious, and, when not in flower or fruit, it is almost or quite impossible to distinguish the male from the female plants. The yellowish red fruit comes before autumn, and, though it remains ripe on the plants only a few days, it adds much to their beauty. The foliage, nearly smooth and green above, covered with rusty scabs underneath, is pretty on the wild plants; but when these are established in the nursery it becomes much larger and more beautiful. On the headlands of Lake Champlain this shrub is quite common, usually along the margins of half shaded cliffs overhanging the water.

Southwick, Mass.

F. H. Horsford.

Seasonable Hints.—Cold frames should be uncovered every fine day and carefully ventilated at all times, or the result will be spindling and enfeebled plants. As soon as the ground is sufficiently dry—that is, when it can be readily pulverized with spade and digging-fork—shrubs, small fruits, hardy herbaceous plants, and the whole line of dormant roots in the kitchen-garden, like Asparagus and Rhubarb, should be transplanted. When Strawberry-plants show signs of returning life, remove the mulch a little from around the crown of each plant, so as to allow the young leaves space to develop. If the bed has no mulch it will pay to apply it even now.

If the lawn was neglected last fall, a light dressing of thoroughly rotted manure, or, better still, some of the standard commercial fertilizers, should be applied. This is the time to sow nearly all the vegetable and flower seeds which should be started under glass. Tomatoes, Peppers, Egg-plants, Cabbage, Cauliflower and Lettuce should be sown in the hot-bed without delay, and three seeds each of Cucumbers and Melons should be placed in a three-inch pot, and the strongest one only allowed to develop.

Pansies may be had for late flowers by sowing seeds now, and for succession a month later. Plants may be had in this way almost as good in September as in April. They require a heavy, rich soil that retains moisture well, and when signs of exhaustion are shown they should be treated with liquid manure. A mulch of sphagnum moss, through which has been mixed a small quantity of pure bone-meal, say two pounds of the meal to one bushel of the moss, will produce abundant bloom.

Cannas should be separated and potted now. The new so-called dwarf varieties, which are really ever-blooming, are among the most effective plants of recent introduction. Tuberous Begonias are growing in favor for garden culture, and they should be started at once, as also should Gloxinias, Caladiums, Achimenes and the like.

Correspondence.

Prairie Forestry.

To the Editor of GARDEN AND FOREST:

Sir.—Allow me to make a brief rejoinder to Professor Keffer's remarks in regard to forestry on the plains, in your issue of March 12th. To be sure, without tree-planting in a treeless country, there can be no forestry; yet, while trees and the planting of trees is the necessary basis for forests and for forestry, it should be now understood and urged that the planting of trees alone does not constitute forestry, and unless the work is done with a certain knowledge, and in accordance with certain principles of forestry proper, it cannot produce the results—or at least the full results—which are anticipated. It is the manner of planting which constitutes the difference between mere tree-planting and forest-planting. What we do now on the prairie in regard to forestry bears the same relation to forest-planting proper that the crude, unscientific scratching of the ground for a food-crop, by the Indian or Mexican, bears to the highly intensified methods of the New Englander or European. In a measure and in a manner results are obtained, but neither in a full measure nor in the best manner.

The first and the lasting object and leading thought of the forester is to create and maintain forest-conditions. Such conditions are afforded by dense growth, mixed growth and undergrowth, which combination alone can shade the ground effectually and continually. In order to maintain such forest-conditions it is not enough to plant densely and plant mixed growths; we must know what the component parts of our plantation will do in their further development, how they will grow up in relation to each other; how, in fact, they will keep up forest-conditions and develop into a desirable wood growth; we must plant with a foresight into the future of our plantation, if we wish to deserve the name of forest-planters. To do this we must have a knowledge of the life-history of our forest-trees, their requirements, their rate of growth and development during the various stages of their life.

I have no fear that we will not learn all this in time, but so far we know but little about forestry methods as applied to our forest-trees, and even the little knowledge we do have in this direction finds no widespread application in practice, and I must consider it unfortunate that this is so, and that tree-planting is so often considered synonymous with forestry.

I hope I have made clear my proposition—that it is the absence of forestry principles and forestry methods and not the deficiency in volume of planting which deprives our tree-planting in the west of its right to the title of forestry, although, in the end, for climatic effects, the volume alone will tell. I agree most readily with Professor Keffer that it is the enormous evaporation and dissipation of moisture, due to the unchecked winds much more than to the deficient rainfall, that makes agriculture precarious on the western plains, and hence the more need of creating extensive forests and forest-conditions in that region.

Washington, D. C.

B. E. Fernow.

Orchids at Flatbush, Long Island.

To the Editor of GARDEN AND FOREST:

Sir.—In the neighborhood of Flatbush and Brooklyn several good collections of Orchids can now be found, and, as if to refute the notion that Orchids can only be grown in a house especially built for them, we find them in Palm and Fern houses, and growing with luxuriance in company with these plants. I lately saw a fine show of bloom in the houses of Mr. William Brown, of Flatbush. As is usual at this season, *Cattleya Trianae* made the most striking display, with many well flowered specimens in the best condition and in several very distinct and attractive varieties. A plant of *C. Gaskelliana*, in full flower, was very noticeable, being entirely out of season, for a species whose normal period of bloom is in the months of July and August. Mr. Bennett, the gardener, states that this plant blooms regularly at this season, which makes it a valuable acquisition, and, moreover, it is deliciously fragrant. Among the Dendrobiums were some large and well flowered examples of the old, but still popular, *D. nobile*, and hanging from the roof was a fine piece of the pretty *D. Devonianum* carrying 200 flowers. Other species, such as *D. Wardianum*, *D. thyrsoflorum* and *D. fimbriatum*, were equally well flowered.

The Phalænopses in this collection are very thrifty, and many fine and well branched spikes were seen of the beautiful *P. Schilleriana*; also several good forms of *P. amabilis*, *P. Sanderiana* and *P. Stuartiana*. From the roof hung a fine

piece of *Dendrochilum glumaceum*, bearing forty spikes of its fragrant blossoms, and several plants of the pretty *Oncidium sarcodes*, attached to blocks, had produced well branched spikes loaded with yellow and brown spotted flowers, and forming a delightful combination with the other occupants of the house. *Phajus Wallichii*, too, was in fine condition. *P. grandifolius* was just past flowering, after having made a grand display for several weeks.

A number of well grown Cypripediums added to the display, including, amongst others, the white flowering *C. niveum*, large plants of *C. Boxallii*, *C. villosum*, *C. hirsutissimum*, *C. Harrisianum* and *C. Stonei*. Several plants of note promise a fine show of bloom later in the season, among them being remarkable examples of the true Majus form of *Oncidium ampliatum*. This grand species is always an attractive object when in bloom, bearing great quantities of golden yellow and brown spotted flowers on its many branched stems. Several plants of *Oncidium Papilio majus* were also showing, together with *Cymbidium eburneum* and *Zygopetalum crinitum*. The *Nepenthes* in this collection are always worth a visit, being in fine health. Among them was a good plant of *N. Amesiana*, with several enormous pitchers; also *N. Rafflesiana*, a splendid, well furnished plant of *N. Tildeniana*, with excellent examples of *N. Dominiana*, *N. Craigiana*, *N. Hookeriana*, *N. Sheltonii*, *N. Bennetiana* and many others.

Summit, N. J.

A. Dimmock.

Specimen Plants at Wellesley.

To the Editor of GARDEN AND FOREST:

Sir.—In the *Gardeners' Chronicle* for February 8th mention is made of a remarkable *Cymbidium eburneum* twenty years old, which produced twenty-seven flowers a year ago; and in the next issue of the same paper two plants of *C. Lowianum* are mentioned, one of which had 140 and the other 108 flowers.

It is the common opinion that there are many Orchids grown on the other side which surpass any grown here; but if every remarkable specimen in American collections was accorded a public notice we might find that the superiority of the Old World in this respect is not so marked as we had supposed. Just now in the collection of Mr. H. H. Hunnewell, at Wellesley, Massachusetts, there is a *C. eburneum* with no less than nineteen flower spikes, and one of three large plants of *C. Lowianum* shows 141 flowers, one-half of which are fully expanded. A striking plant is *Medinilla magnifica*, and one not often seen nowadays, though it is by no means new. The specimen, here, a standard with a stem five feet high and a head seven feet in diameter, has thirty-three racemes of flowers, and is an object of great beauty. Perhaps these plants are worth putting on record, and it is to be hoped that other gardeners will follow with notes on some of the treasures in their charge.

Wellesley, Mass.

F. L. Harris.

A Gardener's Problem.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. Burbidge, in his letter at page 117 of the present volume, conveys the idea that Mr. Moore's treatment of *Nepenthes Rajah* may be quoted in refutation of the views of Mr. Watson; but, perhaps, Mr. Moore had better be allowed to state his own experience. In a paper on "Experiments with Manure in Orchid Culture," read before the Scottish Horticultural Association on January 7th of the present year, Mr. Moore is reported as follows: "Many experiments which have been made, and from which important results have accrued, would never have been undertaken but for the failure of some favorite plant or set of plants. A case in point is *Nepenthes Rajah*; thrice I got this plant, twice I lost it, and the third plant now flourishes. When I obtained it first I was recommended to grow it, if possible, in hot vapor, advice which was frequently repeated to me afterward; but treating it as nearly as I could to these instructions, ended in the death of the plant. On the second occasion I was recommended to grow it in cold vapor; was speciously informed that it could not fail with such treatment; that the fact had been amply demonstrated. Again I adopted the advice given, and again I lost my plant. On the third occasion I merely begged a plant, but did not beg advice; I considered long how I would treat it, my inclination leaning strongly to the hot system. Eventually, I determined to try a "betwixt and between," and brought it to the cool Orchid-house, where there was a moist atmosphere with a minimum night temperature of fifty degrees Fahrenheit. In this house it grew apace, and, what is more important, continues to grow and flourish, so that it is

now a fine, vigorous plant, each succeeding leaf being larger than that which preceded it."

I would infer from those remarks that Mr. Moore succeeded simply by following the bent of his genius, and quite independent of any knowledge he may have possessed of the Bornean climate. The experience of Mr. F. L. Ames' gardener, as reported on page 108, would also point to the minor importance of minute knowledge regarding habitat in this particular case.

Cambridge, Mass.

M. Barker.

Native Shrubs in a Mild Winter.

To the Editor of GARDEN AND FOREST:

Sir.—Thoreau, who was a very keen observer, says, in his journal, that he does not remember to have seen the buds upon indigenous shrubs prematurely started by mild weather in winter.

This statement has been verified during the past season, so far as I have had opportunity to examine. While plants of exotic origin, such as the Japan Quince, the Syringa, European Cornels, Lilacs, Clematis, etc., have awakened to a dangerous degree under the warm sun of January and February, the native Cornels, Alders, Clematis, Virginia Creeper and others remain safely inactive—though growing sometimes side by side with the former.

This is a singular and somewhat significant fact, suggesting, perhaps, that the indigenous growths have inherited, from an ancient line of ancestry, a sense of the fickle and dangerous character of the wintry airs of New England; and that their spring openings, accordingly, are regulated by dates more than by temperatures. Does the rule hold good also among herbaceous perennials? I found *Phlox decussata*, Sedum, etc., an inch or more above ground in February, while such natives as *Trillium grandiflorum* and *Aster Nova Angliæ* keep quietly in bed for a season yet.

It would be interesting to hear from those whose opportunities for wide observation in this particular are of more value than mine. Among the larger plants I do not find the rule applying as fully. The White Maples were allured into thrusting out their tiny and beautiful blossoms in February, and the buds of the Red Maple, American Elm, Beech and some others have been considerably swollen for some time. The Maples are always a sensitive race, however, as the sugar makers are well aware—the others mentioned are not yet, I think, sufficiently advanced to receive injury, even from zero weather.

Dorchester, Mass.

E. S. Farwell.

The Tulip-Tree from Seed.

To the Editor of GARDEN AND FOREST:

Sir.—I wish to raise a quantity of young Tulip-trees (*Liriodendron tulipifera*), and should like to know how to proceed in order to get them from the seed. I sowed some seeds last year and not one came up.

Bucks County, Pa.

S. R.

[As a rule, about one seed in ten of this tree will germinate, and even this limited fraction of the whole never sprouts till the second year. Mr. Jackson Dawson's plan is to take a box of good size and fill it with seed and fine sand in alternate layers, and then bury the box in a well-sheltered place, and leave it there one season. The next spring the box is lifted, the seed is taken carefully out, sown thickly in rows and covered lightly. Mr. Dawson read a paper on propagating trees and shrubs from seed at a meeting of the Massachusetts Horticultural Society on March 7th, 1885. The paper was published in pamphlet form, and it contains information of practical value to every one who wishes to raise seedling-trees or shrubs.—ED.]

Periodical Literature.

Only a few years ago references to our vanishing forests were rare in print, and were principally confined to scientific journals. But to-day one can hardly take up a newspaper or magazine without finding some insistent plea for forest-preservation, based on definite knowledge of the damage which has already been done and a lively sense of the imminent greater damage to come. An example in point is an excellent article called "The Forestry Problem," by Mr. Charles Morris, published in the February issue of *Lippincott's Magazine*. The facts it cites are chiefly drawn from the Census reports of 1880; and bad as they are, the reader would be

shocked indeed had it been possible to gather data as full to-day, and to contrast the ruin of 1880 with the wider ruin of 1890. Of course the subject is too familiar to our own readers to justify an abstract of Mr. Morris' article. We need only quote one paragraph as touching upon a cause of injury which is, perhaps, less justly estimated by the public than the lumberman's axe and the camper's fire. This is the forest-browsing of animals. "It is common in the southern Atlantic States," says the writer, "and in California to turn cattle, sheep, horses and hogs into the woods to pick up there a scanty subsistence. The result is the destruction of seedling plants in immense numbers, while young trees, and often old ones, are killed by the loss of their bark. Hogs add to the ruin by rooting up the young Pines and feeding on their succulent roots. . . . At the opening of the dry season in California immense herds of cattle, horses and sheep are driven into the mountains to graze, and from the foot-hills to the highest alpine meadows not only every blade of grass, but also every seedling tree, is destroyed. The present forests await the axe, but the hopes of future forests are ruined. Nor is this all. The sharp hoofs of the sheep, winding up the steep acclivities, tread out the roots of the grasses and other perennial plants; the soil, deprived of its vegetable covering, is washed away by the rains; and not only is the possibility of future forests destroyed, but the fertile plains below are threatened with burial under the gravel and sand swept from the bare mountain-sides."

In *Harper's Magazine* for March Mr. Charles Dudley Warner humorously deplores the recent rise of the Chrysanthemum in fashionable favor, and thinks it imperative upon him to declare that it is less beautiful than the Rose, and to predict that after a while the Rose "will become again the fashion and be more passionately admired for its temporary banishment." If he had consulted facts instead of his own imagination, he would have known that, despite this vogue, there was never a time when Roses were so largely in demand as now. Chrysanthemums have not pushed them out of favor; they have merely won themselves a place which, before they came, was empty; for, as Mr. Warner might have remembered, the Chrysanthemum season is the very season when Roses are at their worst and it is most difficult to obtain them. In early summer they bloom for us out-of-doors; in winter and spring the hot-house supplies them; but in autumn what did we have before the Chrysanthemum was a favorite? Moreover, there are Chrysanthemums and Chrysanthemums, and while we often see flowers with little but size or eccentricity to recommend them, multitudes of varieties are truly beautiful in form as well as color. It is quite unjust to say in a general way that the Chrysanthemum "goes along with all the conceits and fantastic unrest of the decorative art" of the moment, and "helps out our age of plush with a flame of color." Is it not the favorite flower of the Japanese, who, above all other peoples, are remarkable for sobriety in household adornment? Of course it can be misused, but so can the Rose itself; and if any flower may be taken as an emblem of the extravagance and display which too often characterize American homes and entertainments, one could more justly cite the costly hot-house Rose, despite its sentiment and its "capacity of shyly and reluctantly unfolding its beauty," than the cheap Chrysanthemum, although it may be true that "there is nothing shame-faced or retiring about it."

Recent Plant Portraits.

Botanical Magazine for February:

PODOPHYLLUM PLEIANTHUM, t. 7098; a native of Formosa, and a near ally of our Mandrake or May Apple, from which it differs by its axillary flowers and isomerous stamens and petals; and is also interesting in departing from its congeners in having numerous deep purple colored flowers. *P. pleianthum* was discovered in 1881 by Mr. T. Watters, and was introduced into England from the Hong-Kong Botanic Garden in 1885 and flowered at Kew in August last year.

COTTONIA MACROSTACHYA, t. 7099; a small-flowered Indian Orchid of considerable botanical interest, although the flowers are not showy or of much value from a decorative point of view.

DROSER A CISTIFLORA, t. 7100; the most beautiful of all the cultivated Sundews, with bright scarlet flowers. It is a native of the south-west corner of south Africa, whence living plants were introduced to Kew by Miss North, the distinguished botanical artist, whose gallery of flower paintings, made in all parts of the world, is one of the chief popular attractions of the Royal Gardens.

CHIRONIA PALUSTRIS, t. 7101; a south African representative of the Gentias, with rosy pink flowers, and distinguished from

the other species of the genus in its strongly twisted anthers, approaching in this way the European *Erythroca*. It was introduced into England by seeds collected in south Africa by Mr. William Watson in 1887.

CYPRIPIEDUM ROTHSCILDIANUM, f. 7102; a native of New Guinea, whence it was imported by the Messrs. Sander & Co., of St. Albans, a few years ago. The editor, Sir Joseph Hooker, discussing the antiquity of the genus *Cypripedium* and the variability of individuals of the same species, takes occasion to say: "The subject of the antiquity of a genus or group of plants is a very attractive one, and far too complex to enter on here. Such antiquity, when leading to extinction, is supposed to result in fixity of type, in rarity of individuals, and in the restriction of these in area. In respect of it I may allude to the singular fact that though *Cypripedium* is one of the few tropical genera of Orchids that inhabit both the eastern and western hemispheres, it has not hitherto been found in Africa or Madagascar, countries which have on plausible grounds been held to have been the most recently peopled with plants."

Notes.

The annual spring exhibition of the Pennsylvania Horticultural Society will begin at Horticultural Hall, Philadelphia, Tuesday evening, March 25th, and continue until Friday.

At a recent meeting of 700 under-gardeners held in Berlin a unanimous vote was given in favor of an eight-hour labor law, and of setting apart the first of May as an annual workmen's festival.

The most interesting "congress" that will form a feature of the great horticultural exhibition to be held in Berlin this spring will undoubtedly be the meeting of students and growers of conifers which is announced for the 28th of April.

Jasminum nudiflorum has been opening its blossoms sparingly nearly all winter in Central Park, and last week the long wands thickly studded with blossoms could be seen in many places above the snow. While the plant at this season lacks foliage, the contrast of the flowers with the dark green color of the bark is very pleasing.

One of the best known flower painters in Europe, Anton Hartinger, died recently at Vienna in his eighty-third year. His chief work was the preparation of water colors for reproduction in costly books, the last upon which he was engaged being an atlas representing the flora of the Alps to accompany the text of Professor Della Torre.

Mayor Hart, of Boston, has written to city forester Doogue requesting him to make flower-beds on the Common and in the Public Garden which shall imitate in form and color the United States flag, the Massachusetts coat of arms, the seal of the City of Boston, and the badges of the Loyal Legion, the Woman's Relief Corps and the Sons of Veterans. And yet it has been asserted and believed that Boston is a city of culture and refinement.

The Department of Agriculture has recently issued a circular, prepared by Mr. Fernow, which is sent out with the tree seeds that are distributed. The circular gives in brief such suggestions as to the raising of forest-tree seedlings as will be helpful to those not familiar with the practice. Of course the entire theory of raising trees from seed cannot be given in three pages, but the elementary principles seem to have been carefully elucidated so far as the space will permit. The care of seedling-trees in the nursery is to form the subject of another circular.

To illustrate how Peas are influenced by the soils in which they grow, Professor Bailey, in a late bulletin, gives these facts concerning a plot of Golden Gem Peas in the garden of the Cornell University Experiment Station. The rows began in a good rich loam and ran into a stiff and strong clay. A good sod had been turned under a few days before the Peas were sown. The ends of the rows were so dissimilar at picking-time that they appeared to be planted with different varieties. The average height of the plants in loam was eighteen inches; average number of pods to the plant, five and a half; all the pods, except sometimes the very uppermost ones, were ripe, and there were no flowers. The plants on clay were larger, deeper green, with more bloom, and a tendency, not apparent in the other case, to produce two pods on a peduncle. The average number of pods to a plant was seven; only about two-thirds of the pods were ripe, and there were still some flowers.

A young Englishman, in business in Manilla (one of the Philippine islands), interested himself at odd times in growing Orchids, collecting *Phalænopsis* and *Ærides* from the wilds, and fastening them to a tree-trunk in his garden. He sent small pieces to his friends, but only partial success attended these distant exportations. He therefore determined to cut down a tree and export the trunk with these epiphytes thickly growing all around it. The trunk came to England safely, with the clinging little plants all about it, full of life, after a journey of some 10,000 miles, and it may now be seen in the stove greenhouse of Mr. J. Andrews, Manilla Lodge, Fallowfield, standing five feet high and three feet in girth, as a trophy-column to the tact and discrimination of this young amateur. A correspondent of the *Northern Gardener*, who tells this story, adds that the handsome leaves and thick roots almost hide the bark of the trunk; and for general healthfulness he doubts whether anything in the country can equal it.

Dr. Fisher expresses a doubt whether the bee is at best the enemy or the friend of the seed-grower, as he is largely both, for without his work in carrying pollen the fruits of dioecious plants would not be fertilized, and without it, also, his mischief in mixing new varieties with inferior sorts would not be accomplished. It is true that he will give a dose of cucumber flavor to a crop of cantaloupes, if the two sorts of *Cucurbitaceæ* happen to be planted near neighbors; but, then, he offsets his bad work by producing new varieties which are sometimes of very great value. This work may be better and more wisely done by the horticultural philosopher, who acts designedly by combining size and hardness on the one side with delicacy and productiveness on the other. This form of lottery has a few grand prizes, but a far greater number of small ones and blanks; the uncertainty of the drawing adds to the interest of the investment. The farmer oftener than the philosopher offers a new variety which the little bee has helped him to produce the year before, and of which he has known nothing until his eye has discovered the distinguished stranger among his melons, cucumbers or other ground fruits.

In a recent bulletin from the Cornell University Experiment Station, Professor Bailey states that the Crandall Currant, which was supposed by its disseminator to be a hybrid between the Missouri Currant and the common Red Currant, is really a variety of the Buffalo or Missouri Currant (*Ribes aureum*), with no indications of hybridity. It does not appear to be a well fixed variety, some of the bushes on the experiment-grounds yielding berries but little larger than the common Red Currant, while others bear fruit five-eighths of an inch in diameter. The plant seems variable also in its time of ripening. The bushes are vigorous growers, need more room than ordinary Currants, and seem now more free from insect depredations. The fruits are fair, polished, bluish black, easily separated from the stem, and therefore picked singly like gooseberries or cherries. Their flavor is agreeably sweet, but lacks character, but has none of the grossness of ordinary black currants. This currant is good for culinary purposes, both when green and ripe, and for jellies it is preferable to the ordinary kinds. The variety is quite distinct, representing a new type of small fruit, and when further selected and improved must become a staple.

The portrait of a splendid specimen of *Eucharis Amazonica* with 220 blooms is published in a late issue of the *Gardeners' Chronicle*. It was grown in the gardens of Mr. G. F. Linden, of Birmingham, and shows such exceptionally good cultivation of a plant which is often difficult to grow successfully, that the methods under which it was produced are worth attention. The specimen was grown in "soil composed of good loam, a little leaf-soil, some broken sandstone, and a few half-inch bones, with plenty (quite six inches) of drainage to allow water to escape freely." The roots were found to adhere to the sandstone and evidently derived benefit from it. "The plant was kept through the winter and spring in a temperature of sixty to sixty-five degrees, but was removed when it flowered to a cooler house, in which, if kept too long, however, the foliage suffers and decays. Very little water, and that manure water, is used directly on the soil, and then only in hot weather; but the foliage is frequently syringed with clear manure-water, used freely in the growing season, and the plants are never allowed to dry off." Mr. Bluck, the gardener who produced this specimen, thinks that too much soil in the pots and too much water at the roots is injurious to *Eucharis*, and he trusts more to the copious syringings with weak manure-water than to anything else to secure these results. Diseased bulbs of *Eucharis*, sent to this garden, were washed and placed in a pan of sand with sphagnum at the bottom, when they grew freely and were soon restored to health.

"A Gardeners' Problem."

IN the latest number of the *Gardeners' Chronicle* received here the editor announces that the entertaining, though somewhat roving, discussion which has covered whole pages of our valued contemporary ever since the year began, is now brought to a close "in the absence of any new evidence on either side." Since the reverberations of the controversy have been heard in our own columns, it may not be inappropriate to state just what this "Gardeners' Problem" is which has aroused the botanical talent of the old world into such general activity. The *Kew Bulletin* for December last contained an important report by our correspondent, Mr. Watson, on tropical and sub-tropical plants grown in the open air in southern Europe, and this was prefaced by a note in which Mr. Dyer, Director of the Royal Gardens, said: "Horticulture is essentially an empirical art. Botanical science can afford little *a priori* information as to the cultural conditions which any plant will require or tolerate; these for the most part can only be found out by trial and experience." This paragraph was pronounced by Dr. Masters as discouraging to those who believe that practical horticulture has a right to look to vegetable physiology and anatomy for guidance and for profitable suggestion, and he added that the statement of Mr. Dyer was too absolute. These, so far as we now remember, were the most positive declarations ventured on either side, and the various disputants assumed positions somewhere between these extremes, and usually about equidistant from each. The problem, from its nature, does not admit of demonstrative reasoning, and therefore remains unsettled. This fact, however, does not deprive the discussion of a genuine value, for each writer endeavored to illustrate some phase of the question by examples of plants in actual cultivation, so that a body of experience has been collected which will prove of assistance to all who are interested in the practice or theory of horticulture.

In studying the argument in the case of Empiricism *vs.* Botanical Science, it may be worth while to remember that knowledge is knowledge, whether it is acquired by cultivating plants or by studying them in some other way. Any one who attempts to build a sustained argument based upon the

assumption that knowledge which is practical can be separated by a distinct line from knowledge which is scientific, will be likely to come to grief. We do not mean by this that there was a general confusion of terms in the discussion of this gardeners' problem, but it seems like drawing a rather fine distinction when it is said of an author that he speaks as a gardener on one page and as a botanist on the next, and that in the one case his utterances, drawn from the stores of his empirical knowledge, are helpful to the cultivator, while in the other case his counsel, based on scientific knowledge, has no practical value. When it is stated that the gardener who has a genius for his work will "naturally hit upon the right method" of cultivation; and again, that the good gardener will "know instinctively" what treatment to apply in a given instance, this means that the gardener has been doing just what the man of science would have done if he had been engaged in research in the same field. He has been making deductions, classifying, generalizing. What is called his instinct is the result of reasoning from data gathered by observation, and his conclusions may be strictly logical, although he has never thought of formulating them.

In regard to the general question it may be said that in this country there are some persons who are apprehensive that farmers and gardeners will be unfitted for the practice of agriculture and horticulture if they are subjected to instruction in the sciences related to these arts. The foundation of so many agricultural colleges, with chairs of horticulture, would seem to indicate, however, that what the country at large is afraid of is not too much science, but too little. It is true that very many of the marked advances in agricultural and horticultural practice have been made by actual workers in the field who have found by experience that certain methods and processes could be improved upon. These steps forward have not been due, as a rule, to men of science, but it is equally true that science has always been ready to present the reasons for the change, and in this way to suggest the most hopeful lines for further improvement. It seems to our people that a man who knows why he adopts a given method of cultivation is likely to be a more practical cultivator, less likely to fail in the essentials of the practice, than one who blindly follows the rule of thumb. Horticulture and agriculture, too, are no doubt largely empirical arts; but we sympathize with Dr. Masters in the belief that the addition of scientific knowledge will help to place them on a foundation more sure and productive than that of individual experience.

We cannot expect that every farmer and gardener will become an expert in vegetable physiology, but it is reasonable to hope that intelligent cultivators will acquire so much of the elements of the science as are set forth, for example, in Professor Johnson's treatise, "How Crops Grow," and there need be no fear that the little knowledge thus gained will prove a dangerous thing. Neither farmer nor gardener needs to be so well schooled in chemistry that he can make a quantitative analysis of a soil, or of a food ration, or of a fertilizer; but he should know enough of this science to be an intelligent student of the current literature of the experiment stations. Indeed, one can hardly visit a farmers' institute in this country without hearing the more successful farmers talk intelligently about nitrogen, phosphoric acid and potash, or of carbohydrates and albuminoids, and these farmers will testify that this elementary knowledge has directly improved their practice. The students of mycology and entomology have rendered incalculable benefit to horticulture by discovering remedies for plant-diseases and destructive insects, and the gardener and farmer are certainly better equipped for an encounter with the black rot of the Grape or with the curculio, if they know enough of the history and habits of fungus or insect to understand why a given method or a given season is selected for the application of the remedy. And so we might go through the entire list of sciences related to horticulture, and fail to discover one, an elementary

knowledge of which would not prove of distinct advantage to the gardener or farmer.

There are, no doubt, gardeners, as there are men in other walks of life, whose practice is hampered or misdirected by what they think they know; but it is hardly fair to lay the blame for such failure at the door of science.

• Legislation Against the Gypsy Moth.

WE believe that the bill looking toward the extermination of this insect, now before the Massachusetts Legislature, should receive favorable consideration. The caterpillar of the Gypsy Moth is known to be a destructive pest in the gardens and orchards of Europe, and it has evidently, within the twenty years since its unfortunate introduction into Medford, obtained a firm foothold, and unless it is repressed, it will perhaps spread throughout New England and the Northern and Central States. The amount of \$25,000 asked of the General Assembly will, a few years hence, seem a not extravagant sum, should the insect be at once exterminated, a matter not difficult of accomplishment, if the suggestions made by Professor Fernald in his pamphlet issued by the Massachusetts Experiment Station are carried out.

The chief value, however, of this particular measure would be that it might lead to the passage of a general act against insect depredators. Massachusetts has been liberal in the publication of illustrated works on injurious insects, such as Harris' Treatise on Insects, and the amounts expended in this direction have been a good investment. The General Government, too, has made liberal grants to the State Experiment Stations; but unless the people of each state co-operate in applying the practical remedies against these pests, they will continue to be an exhaustive drain on the resources of farmers and fruit-growers. Had the Legislature of Massachusetts in the early part of the century passed acts, with suitable appropriations, against the tent-caterpillar and canker-worm, how much desolation of orchards and loss of shade-trees might have been prevented! Even now, every June as one travels from Boston to Portsmouth, or in any direction from Boston, he beholds ravaged orchards and leafless trees, which look as if a fire had passed through them. A few orchards are saved, and it has been again and again demonstrated that with a little care and slight expense an Apple orchard can be easily preserved from the attacks of caterpillars. But when a few keep these pests away by the use of simple preventives, their careless neighbors take no precautions and suffer their shade-trees and orchards to be worm-ridden. The result is that the worms are transported by the winds over fences from infested Elms; the females climb over fences, and thus vitiate the best laid plans of the more public-spirited planters. A law compelling the indifferent or careless to co-operate in staying and preventing the ravages of these pests might accomplish a great deal toward reducing their numbers. And why should there not be legislation against insect pests, as well as game-laws or dog-laws or acts against allowing cattle to run at large or permitting noxious weeds to go to seed?

Whatever may be the tendency to over-legislation in our country, it is a reasonable course to compel every landholder to co-operate in preventing these insect ravages; for if the owners of leafless orchards and defoliated shade-trees are permitted to maintain insect-nuisances, they will defeat every effort of their more enterprising neighbors who are willing to take measures for protecting their trees.

The Cypress of Montezuma.

THERE appeared not long ago in these columns (volume iii., page 2) an account of the deciduous Cypress (*Taxodium distichum*), with a view of a swamp in southern Indiana covered with a forest of these trees surrounded by their peculiar root growths, the so-called Cypress-knees.

The illustration on page 155 of this issue represents the trunk of a tree of the same species and one of the most interesting and best known trees in America, the "Cypress of Monte-

zuma," the largest of the famous Cypress-trees in the gardens of Chapultepec, near the City of Mexico, and a noted tree nearly four centuries ago. It belongs to the same species as our deciduous Cypress of the Southern States, which extends southward through some of the high valleys of Mexico nearly to Guatemala, growing in these southern stations in comparatively dry ground, and without producing the knees which characterize the more northern trees, the inhabitants of deep swamps and inundated river banks. The "Cypress of Montezuma" is a tall and still graceful tree, rising to a height of 170 feet, with a trunk to which different travelers have ascribed a girth varying from forty to nearly fifty feet, the discrepancies in the measurements being due, no doubt, to the different points above the surface of the ground at which they were made. It stands near the hardly less famous spring, the "Bath of Montezuma," the source of the water supply of the Aztec capital, to which it was carried on a splendid aqueduct of 900 arches.

The tree of Montezuma is only one of a number of individual Cypress-trees growing in different parts of Mexico, famous for their antiquity, their vast dimensions and the historical associations which cluster about them. Distinguished naturalists* have examined their history and computed their age, which, in the case of the "Cypress of Montezuma," has been estimated to be about seven centuries; while that of the larger tree of Santa Maria del Tule is believed to be nearly 2,000 years old. This tree, the largest deciduous Cypress of which there is any authentic record, stands in the centre of the village of Tule, on the road from Oazaca to Guatemala by the way of Tehuantepec, within the enclosure of the parish church, and is a conspicuous object from all the country round. The measurements of this tree given by travelers vary a great deal, and it is difficult to compare them satisfactorily, as they generally lack precise information of the exact manner in which they were made. The latest measurements of this tree which we have seen were made a year ago and are as follows: Circumference of the trunk five feet from the ground, following all its sinuosities, 146 feet; actual circumference five feet from the ground, 104 feet; total height of the tree, 150 feet; longest diameter of the trunk, forty feet; shortest diameter of the trunk, twenty feet; spread of branches, 141 feet.

Hardly less famous than the Cypress of Santa Maria del Tule is the Ahuehuate of the village of Atlisca, near Puebla, of which the worthy Archbishop wrote three centuries ago, as quoted by Gray: "The cavity of the trunk might contain twelve or thirteen men on horseback; and that in the presence of the most illustrious Archbishop of Guatemala and the Bishop of Puebla more than a hundred boys entered it." This tree, according to Humboldt's measurements, had in his time a trunk girth of sixty-six English feet, the cavity of the trunk being about sixteen feet in diameter.

"El Arbol de la Noche triste," the Tree of the Night of Sorrow, another of the great Mexican Taxodiums, stands in the little village of Popatela. It marks the spot where the soldiers of Cortez went down like sheep before the Aztec hordes, their backs to the foe. The trunk of this tree girths about sixty feet, and although the top and many of the branches are in a state of advanced decay, the tree still rises above the little church close to which it stands and which was built to commemorate the battle.

Our illustration of the trunk of the "Cypress of Montezuma" is made from a photograph taken by Miss A. L. Rotch, of Boston, to whose kindness we are indebted for its use.

Holiday Notes in Southern France and Northern Italy.—XIII.

NEARLY twenty miles south-west of Nice is the pretty town of Cannes, a wonderful horticultural centre. The principal promenade is that of La Croisette, which, as far as the beauty of the trees is concerned, is preferable to the famous Promenade des Anglais at Nice. Date Palms alternate with *Platanus acerifolia*, and here and there large Oleanders are thriving between their more majestic neighbors. The Planes do remarkably well close to the sea. Apparently self-sown, high up in the chinks of rocks and walls on the way up to Mont Chevalier, *Solanum glaucum* was perfectly at home, growing very freely and flowering abundantly. From the top of the hill just named a series of fine views are obtained, especially of the Iles de Lérins, in the largest of which, Ste. Marguerite, that mysterious individual—the man with the iron mask—was confined from 1686 to 1698. In our own times, Marshal Bazaine

* Humboldt, "Essai Polit. Nov. Esp.," ed. 2, ii., 54.—A. De Candolle, in *Bibl. Univ. de Genève*, xlvii., 392.—A. Gray, "Scientific Papers," ii., 113.

was imprisoned here from December, 1873, until his escape in August of the following year.

Orange-trees are largely grown at Cannes, principally for their blossoms; the real centre of the Provençal perfumery distillation is, however, at Grasse, about a dozen miles inland from Cannes. Cassie (*Acacia Farnesiana*) is also extensively cultivated on the hills outside Cannes; the plants are kept pruned in like large gooseberry-bushes.

One of the glories of Cannes is the beautiful *Acacia dealbata*, which, as described so charmingly by Alphonse Karr, has "for leaves the finest ostrich plumes, and for flowers great golden thyrses." Enormous quantities of the flowering branches of this species are forwarded during the winter months to the Paris, London and other markets, and as the flowers stand traveling well and last a long time, they can be bought at a cheap rate from the costermongers in the streets of London and the neighboring towns. The soil of Cannes is a micaceous schist which suits this *Acacia* admirably; at Nice and elsewhere along the Riviera, wherever limestone abounds, it obstinately refuses to grow. According to Alphonse Karr, a line a yard wide, drawn between the territory of Nice and that of Cannes and St. Raphael, marks the boundary where the soil suddenly changes in character; on one side of this line the *Acacia* in question luxuriates in company with tall Heaths (*Erica arborea*)—three yards and upward in height—which in January are covered with white blossoms, exhaling a perfume that partakes of the character of vanilla as well as that of bitter almonds. On the Nice side of the line neither this *Acacia* nor Heath can even be made to grow.

Fine Stone Pines and Cork Oaks form striking objects in the Villa-gardens on the hill-sides, and in uncultivated ground the underwood is Myrtle, Heaths, spiny members of the Broom family, Smilax, Phillyrea, Lentisk, *Lonicera Caprifolium*, Cistus, etc.

Solagnac's establishment on the "Californie Hill" is the most important and best managed of the gardens mainly devoted to the culture of plants on a large scale for cut flowers. Terrace after terrace—many of them only just broad enough for the long houses filled with Roses, etc.—are kept up by stone walls and rise in long series one above the other. Peaches, grown as bushes, gave promise of a fine crop of fruit, and underneath them were planted such things as *Iris Susiana*, *Gladiolus Colvilli* and other bulbous plants with showy flowers. Large quantities of Mignonette were coming on—sown toward the end of August, the seedlings had four or five leaves the third week in September and would begin to yield a crop of flowers in December.

The favorite Carnation was "Enfant de Nice," a sturdy, compact grower, with fine flowers, white, with a blush-colored centre. The two Strawberries grown by Solagnac are Victoria and Dr. Morère. Probably some of the readers of GARDEN AND FOREST will remember the fine dishes of the latter variety exhibited at Paris—in the horticultural exhibition from May 24th to May 29th, in connection with the exposition—and the statement written on the card, that the fruit had borne a journey of about 630 miles.

The Roses were nearly all Teas, and were planted out on the terraces above mentioned. During the summer months the lights are taken off and are only replaced at the end of September. Comparatively little pruning is necessary, the long, vigorous shoots being tied down in a more or less horizontal position. Some 8,000 lights were piled in blocks at the time of our visit; the supports and framework of the houses—at any rate, those in which the Roses were grown—were made of pitch pine, unpainted. Excellent arrangements, some of them very ingenious, existed for a copious water supply on all the different levels in this thirsty spot, and everything evinced the pride the proprietor feels in his garden. Not a weed was to be seen, and all the plants were healthy and well grown.

After leaving Cannes, we passed St. Raphael in a ravine on the coast. Then comes a romantic rocky district with numberless Mulberry-trees and vineyards in which Phylloxera was playing sad havoc. The Olives were pollarded as in Languedoc, and looked stiff and formal in comparison with the beautiful trees on the Italian Riviera. Fields of Tuberose just coming into flower were passed here and there. Along the coast heaps of snowy salt marked the spots where in the low, marshy grounds the sun's rays had been utilized for procuring this necessity of life from the sea-water by evaporation.

But my holiday was nearly over, so a comparatively short stay was made in Marseilles; another stop at Lyons, not long enough to make my scattered notes worth recording here, and then a rush to London to resume duty after nearly a month's absence.

Entomological.

A Newly Imported Rose Saw-fly

(*Emphytus cinctus*, L.)

ONE of the natural and inevitable results of the great increase in importation of plants, bulbs, etc., from foreign countries is the introduction with the plants of some of the insects which live upon them. These insects may also be introduced in other accidental ways, and, like some foreign weeds, it frequently happens that the immigrants thrive better and prove more troublesome in their new surroundings than in their native home.

The importation of an additional enemy of the Rose has now to be recorded, and whether or not it is to be as troublesome as some of its predecessors remains to be proved. In the summer of 1887 I found a number of Saw-fly larvæ, which I had never observed before, on the under side of the leaves of several species of Rose at the Arnold Arboretum and on a few horticultural varieties of the Rose in some gardens in the vicinity. In the following summer and autumn the larvæ were quite plentiful, and they were found in the Botanic Garden at Cambridge as well as in the Arboretum and other gardens in Boston. I do not know how much further their present range extends, but it may be safely stated that in the localities mentioned, and where the injuries by Saw-fly larvæ were noticeable during the seasons of 1888 and 1889, fully one-half of the defoliation of the Rose-bushes was caused by this imported species, the remaining portion of the injury being chiefly the work of the well known Rose-slug (*Selandria Rosa*, Harris).

The difference in the character of their depredations may be readily seen, as the larva of the imported Saw-fly generally begins at the edge and eats all parts of the leaf to the thick part of the midrib, whereas the Rose-slug usually devours the green tissues of the leaf only, and leaves a more or less perfect skeleton of it. The larva of this newly imported Rose saw-fly also has the habit, when at rest on the under side of the leaf, of curling up its body into a close spiral or ball, with the anal segments resting on the middle part of the body, a position never assumed by the common Rose-slug.

The fully grown larva is about three-quarters of an inch long, smooth, cylindrical and tapering slightly from the head. The head is dull yellowish orange in color, with a brownish or blackish stripe down the middle of the top, and with black eyes. The color of the body is a metallic green above, though sometimes pale; and the lower part of the sides, the under side of the body and the legs are grayish white. Above the spiracles there is a dark spot, which, in some stages of the larva, appears as a dark stripe along each side of the body; and there are other spots close above the legs.

It was not until the autumn of 1888 that a few perfect saw-flies were raised from these larvæ, and, at first being supposed to be a native species, it was some time before they were identified. Finally, after reference to descriptions of European species, there seems to be no doubt that this is *Emphytus cinctus*, L., a species known to occur over the larger part of Europe and to extend into Siberia.

The color of this Saw-fly is shining black; antennæ, black; thorax with two very small white points (cenchri) behind the second pair of wings; abdomen, a little longer than the head and thorax together, and, besides a somewhat triangular white blotch behind the thorax, there is a conspicuous yellowish white band on the fifth segment of the females, which is absent in the males. This white band does not quite encircle the body, but terminates abruptly after passing around the sides, leaving the middle of the under side of the segment black. Of the legs, the femora or thighs are dark brown or black, with white on the upper part; and the tibiæ are whitish at the apex, the rest of the tibiæ and the tarsi being reddish. The length of the largest specimens (females) is about three-eighths of an inch, and the wings, which are transparent, expand five-eighths of an inch or slightly more.

The ordinary observer may instantly distinguish these insects from the common Rose Saw-fly by their much larger size (two to three times as large) and this white band on the body of the female. They are also much more active than the common black species, of which Dr. Harris says ("Insects Injurious to Vegetation," p. 525), "when touched they draw up their legs and fall to the ground."

The eggs are deposited singly on the under side of the leaves. The Saw-flies may be found hovering about the Rose-bushes early in May, and some larvæ continue to feed until late in October. There are certainly two, possibly three, broods during the season.

Curiously enough, this insect has been considered by some

European observers as a Rose stem-borer, because the larvæ have been found in Rose stems; and, in a "Rose Supplement" to the *Gardeners' Chronicle* for July 7th, vol. viii. (1877), a figure (Fig. 8) is given of this insect under the name of the "Rose stem-boring Saw-fly," in which the Saw-fly itself is well represented, but the figure of the magnified larva shows that it must belong to some other species, as it is covered with bristles or hairs, whereas the larva of *E. cinctus* is smooth. The truth seems to be that the fully grown larvæ, in search of suitable places in which to undergo their transformations, often select the pithy part of the Rose-branches and stems where they have been pruned off and exposed. They never bore independently through the hard, woody part of the stem, and never go deeply enough into the pith to cause serious injury to the stems of the plant. Like the Cornel Saw-fly recently noticed (vol. ii., p. 520), they also select very soft or decaying wood in which to hibernate and pupate. As is the case with many other species of Saw-flies, this one is said to be parthenogenic. Fortunately, the remedy for this possibly troublesome pest is easily procured and applied, and thorough applications of hellebore at the right times will clear the bushes of all larvæ.

The insect was described and well figured by the late Dr. S. C. Snellen von Vollenhoven (*Tijdschrift voor Entomologie*, viii. [1865], p. 73, pl. 3), and a translation of the text by J. W. May was given in the *Zoologist* (Newman's) for 1870, p. 1,993. In Europe an ichneumon, *Cryptus emphytorum*, Boie, is known as a parasite of this Saw-fly. J. G. Jack.

Arnold Arboretum.

New or Little Known Plants.

Aster ptarmicoides.

THIS pretty little Aster, of which a figure appears on page 153—the first which has been published of it—is hardly known in gardens, although, while it is not one of the showiest of the American Asters, it is one of the prettiest and most graceful of them all, and therefore well worth a place in the herbaceous border or in the rock-garden. It is especially well suited to plant among the crevices of rocks, for its natural place of growth is in such situations where it is found from western New England to Minnesota, and then westward to the Saskatchewan country and the mountains of Colorado.

Aster ptarmicoides is a dwarf, rigid plant, the wiry stems varying in height from six to twenty inches, or growing rather taller when planted in rich garden soil. The leaves are lucid on the two surfaces, linear, or the lower ones somewhat spatulate, and three or four inches long. The flowers, which are produced in corymb-shaped cymes, are white.

Aster ptarmicoides was discovered by Mr. Thomas Nuttall near Fort Mandan, on the Missouri, before it was known to be an inhabitant of New England. Botanists have had different views in regard to this plant at different times during the last fifty years, and it has been referred by them to no less than six different genera. A taller and more slender variety of this plant (var. *Georgianus*) has been found in north-west Georgia and in Arkansas.

Foreign Correspondence.

London Letter.

THIS week has been one of extremes as regards weather. It began with a heavy fall of snow accompanied by a sharp frost, until the thermometer fell to ten degrees, or twenty-two degrees of frost. So low a temperature in March has not before been known here within the last fifty years. Wednesday, the fifth, brought a south-west wind and sunshine, and on Thursday the temperature at midday was fifty-five degrees in the shade. Whilst a little cold was wished for to check too forward vegetation, so much as twenty-two degrees when fruit-trees are in bud and even in flower means disaster.

Amongst the plants now in flower at Kew the following are noteworthy:

TACCA ARTOCARPIFOLIA.—This is a most remarkable stove-plant. Tacca is a genus of about nine species, three only of which are known in cultivation: *T. (Ataccia) cristata*, recently noted in GARDEN AND FOREST; *T. pinnatifida*, enonomically interesting, its tubers being described as "resembling new

potatoes" and the fucula from them being known as South Sea Arrowroot (it is also largely used in the same way as Sago for puddings, etc.); *T. artocarpifolia* is the largest of the three. From its tuberous root-stock spring numerous leaves on stalks three or four feet long, the blade two feet across and divided into stalked pinnatifid segments. The flower scapes are erect, six feet high, and each one bears a whorl of leafy bracts surrounding a cluster or umbel of numerous green-brown flowers, which are stalked and elegant in arrangement. Probably the most attractive feature is the numerous long arching brown filaments which spring from amongst the flowers and hang over Medusa-like. This species is a native of Madagascar. It requires plenty of moisture, rich soil and a tropical temperature all the year round. It is not what one would call beautiful; still from its elegant, stately appearance and the extraordinary character of its inflorescence it should rank amongst select plants for cultivation in large stoves.

GODWINIA GIGAS.—I noted this plant when it flowered at Kew last year, and merely mention its flowering again now because hitherto it has not flowered two years in succession. Until the introduction of *Amorphophallus Titanum* Godwinia was far and away the most gigantic of all cultivated Aroids.

CHAMÆDORÆAS.—More than thirty species of Chamædoreas are cultivated at Kew, both in the small houses and in the large Palm-house, where they are effective as well as useful as undergrowth to the large Tree-Palms in the beds. They are even more ornamental in a house devoted almost exclusively to Tree-Ferns, large Aroids and the most striking of the *Marantaceæ*, the Chamædoreas being planted amongst the large leaved Anthuriums and Philodendrons for the sake of contrast and elegance. In addition to the feather-like charm of their foliage there is also the decided beauty and delicious fragrance of their flowers, which are developed freely at this time of year on branching, drooping spikes, in clusters below the head of leaves. In some of the species the flower spikes are not unlike those of the Meadow-Sweet and are quite as elegant. In others, as for instance *C. Ernesti-Augusti*, the female plants bear long unbranched spikes with numerous bright red flowers, the whole spike afterward changing to a coral-red color. Few people think of growing Palms for the sake of their flowers, owing to the fact that most of these plants can never grow to flowering size in ordinary plant houses. But Chamædoreas are exceptions in this respect, as they flower when less than six feet high; indeed, *C. tenella* and *C. pygmaea* are the most diminutive of Palms, flowering and fruiting when only a foot high. *C. scandens* and one or two others are remarkable as climbing species, a character which renders them available for clothing large pillars or growing against the trunks of the largest Palms.

CAMELLIA RETICULATA.—A very fine bush of this large flowered species is now one of the chief attractions in the winter garden at Kew. Camellias have, as a rule, little to recommend them except the stiff symmetry and color of the flowers, but this big flowered species differs from them sufficiently to gain the admiration of the most artistic of flower-lovers. Along with size—for the flowers measure as much as nine inches across—there is the charm of looseness and elegance in the curve and arrangement of the petals, in which characters no two flowers are alike. Then the color, a deep rosy red, with the bunch of golden stamens showing through here and there, is most attractive. The leaves are stout and leathery, not shining, whilst the conspicuous reticulating nerves give them a character by which the plant is easily recognized. According to Mr. Hemsley the proper name for this plant is *C. spectabilis*. It has been in cultivation here about fifty years.

CANTUA DEPENDENS.—There is no more beautiful greenhouse climber than this, but it has a bad reputation in gardens because of its generally falling a prey to red spider and rarely flowering well. When fortunately situated, however, it makes a magnificent show whilst in flower, its elegant trumpet-shaped, bright red flowers hanging in loose corymbs from almost every branch. The finest example I have ever seen was growing against the back wall of a lean-to greenhouse with a south aspect, the Cantua being planted in a border of peat at the foot of the wall. It flowers in the spring. A plant of it is now in flower in the conservatory here.

A NEW HYBRID PHAIUS, raised by Mr. N. Cookson, of New-castle, its parents being *P. Wallichii* and *P. tuberculatus*, is, perhaps, the most interesting Orchid in flower in England at the present time, which is saying a good deal for an Orchid, a hybrid, too. But the plant is of exceptional beauty, both in color and form, whilst in constitution it appears to have inherited the sturdiness and free-growing character of the female parent, *P. Wallichii*. We believe that it is only three years since the seeds were sown from which the plants now flowering

Fig. 27.—*Aster ptarmicoides*.—See page 152.

were raised, and that they have grown vigorously is shown by the strength of the flower-spike and vigor of the foliage. An inflorescence recently sent to Kew by Mr. Cookson had a scape a foot long, and it bore five flowers which were fully four inches across, the segments similar in form and arrangement to those of *P. Wallichii*, two inches long, half an inch wide, their color pale rosy salmon shaded with brown. The lip is almost campanulate, spurless, two inches long, three-fourths of an inch across the mouth, with a tongue-like lobe nearly an inch long, wavy and crisped along the margin. Its color is apricot-yellow, changing to deep crimson in the upper part, whilst the lobe is purple with a yellow line running down the middle from throat to apex. The column is white.

CYMBIDIUM LOWIANUM.—Two gigantic specimens of this noble Orchid, both good varieties, the one bearing thirteen spikes with 320 flowers, the other 211 flowers, nearly every one expanded, have just been sold at auction for twenty-eight guineas and thirty guineas respectively. It is rarely that one meets with such perfect examples as these were. They were in pots about one foot three inches across, and the soil they were growing in was a strong loam simply. Although one of the easiest of Orchids to cultivate, yet this *Cymbidium* does not always flower satisfactorily. It is an open secret that both plants were purchased for the great establishment at St. Albans.

C. LOISE CHAUVIERI.—A plant under this name was offered at the same sale, and although a small example with a single growth, the sum of forty-two guineas was refused for it. The name is said to be Reichenbachian, though there does not appear to be any record of its having been published. Mr. Sander sold two plants of it, the only others known to exist, to Sir Trevor Lawrence about eight years ago, but they have not yet flowered. In the sale catalogue it is described as "a large flowered scarlet variety from Madagascar, the finest new Orchid in existence." A *Cymbidium* with large scarlet flowers would be a grand addition to garden Orchids. Meanwhile we may note that there are no species of *Cymbidium* hitherto recorded from Madagascar, a fact which, however, goes for very little, seeing how few of the plants of the interior of this island are known.

The Cantaloupe.

OF the various members of the Gourd family, those which interest us generally are the plants which supply our tables with delicacies, of which the Cantaloupe has the greatest number of admirers, and, in the estimation of some, it has no equal among our summer fruits. To constitute perfection, the fruit should be removed from the vine shortly before it is ripe; it should be washed with soap and cold water, then dried in a soft towel, and set to ripen in a dry place. A Cantaloupe that before washing smells like a potato, will in a few hours begin to give out an inviting perfume, and when this odor has reached its proper measure and character is the time to cut the melon.

My own ideal melon is of the size and form of a large ostrich-egg, with a thin, finely-netted rind, thick, grass-green flesh, a small seed cavity and a sweet, aromatic flavor. Some fifty years or more ago there was introduced into this market a small, green-fleshed Cantaloupe known as the "Centre Melon," which, for a time, excelled in richness of flavor all of its competitors. It was flat in form, grooved and finely netted; but it was too little to suit the ideas of the trucker, and therefore had to be made larger by hybridization with other flat varieties of greater diameter but inferior flavor. This Centre Melon was the progenitor of the Jenny Lind variety named about 1846; but where it came from no one now appears to know. I am inclined, however, to believe that it originated in the East, and possibly in the table-land of Armenia, where netted, green-fleshed melons are produced in abundance, some of which are flat, and where the same perfect flavor is to be met with. These Armenian melons

belong to a hardy race, are quite productive in our climate, and can stand it quite as well as any of our own kinds; they are as yet entirely unknown to our seedsmen, but have been grown under the severe test of the season of 1889. In form they are flat, globular or oval, the last being seven inches long, and all are fine-grained, thin-rinded, green-fleshed and closely netted, the last an unusual feature in our own varieties last year. This oval Cantaloupe has come nearer to my ideal than any one I have yet tested, and I hope to give it a better trial this coming summer. As Oriental seeds always come mixed in the packages, it will take time to separate the varieties by selection. As I have discovered Erzeroum, in Armenia, to be a great melon centre for both Cantaloupes and Watermelons that are calculated to stand our hot summers, it is to be hoped that our enterprising seedsmen will take steps to secure a full line of seeds, and particularly since my twenty-six kinds of Watermelon seeds were all lost in the wet ground.

The Cantaloupe has largely multiplied in its varieties in our country of latter years, and we have now those that are white-fleshed, yellow-fleshed, red-fleshed and salmon-fleshed. We have also netted, toad-marked and smooth fruits, with green, yellow and whitish rinds. Attempts have been made to grow the winter varieties of Naples and Malta, which may be ripened from Christmas to Easter, but as yet with no encouragement. The large green melon of Naples is the best and grows in boggy land, but has thus far failed when planted in the same form of soil in Florida, under my directions.

In size the Cantaloupe varies as much as in quality, and the extremes of weight are a few ounces and fifty-two pounds, the largest being coarse-grained and somewhat fibrous in texture. Up to twenty or twenty-five pounds fine-grained fruits are produced, especially of the green-fleshed varieties. The largest imported kind was introduced from Portugal, and of native varieties, was brought recently from Colorado, both at their maximum weighing over fifty pounds, and being as large as very large Watermelons. For a combination of large size and fine quality, perhaps no imported variety ever equaled the Persian melon grown for many years in the vicinity of Washington City, under the name of the Hunter Cantaloupe, a long, golden, closely netted fruit, with green flesh, reaching twenty inches in length and a weight of twenty-five pounds. This must not be confounded with the Casaba or Smyrna melon, often erroneously called Persian, the seeds of which were sent to the United States by Dr. Goodell, now of Philadelphia, on several occasions when residing in Constantinople.

Persia is a land of melons, from which we have had, as far as known to me, but four varieties of Cantaloupe, two of which are still produced, and no Watermelon. Who now grows the Ispahan Cantaloupe of the late Bayard Taylor, or the Persian melon of our late President, Mr. Mitchell? These may still exist as hybrids; but in their original character they are unknown here. Travelers praise the melons of Persia, write about them and throw the seeds away. Missionaries and American physicians have occupied the garden-spots of the land of Ahasuerus for half a century; have sent thousands of letters home, and have often visited their own land in person, but where are the Apricots, Quinces, Melons and Pomegranates of their introduction?

My own Cantaloupe tests have been made with seeds from France, the north and south of Italy, Tripoli, Turkey, Turkistan, southern Russia, Russian Georgia, Cappadocia, Armenia, the Valley of the Euphrates, Palestine and Japan. Many melons that are excellent in France and northern Italy will not grow in our climate on account of the heat; those from the land south of Naples do fairly well, but their quality for the table is inferior. The toad-marked melons of north-eastern Italy under repeated tests have always failed, and so have our netted varieties in the cooler parts of that peninsula. Worms and bugs appear to delight in the flavor of the delicate foreign vines, and if the plants should in part escape their ravages, their leaves droop under the sun, and the fruit is not worth cutting. There is something very peculiar in the effects of soil and climate in the production of growth and flavor that we cannot understand. That seeds from cool countries should fail here, and that those from some hot countries should not, we can understand; but why varieties from other hot countries, having a good soil and cold winters, should utterly fail in quality of fruit when it, to a certain degree, grows well, we cannot explain. Of all foreign seeds, I have never seen any that grew so exactly in all respects like our own as those from the world's centre, the ancient land of Ararat, now called Armenia.

Cantaloupes may be divided into two classes: one that

ripens to the best advantage in the house, and the other on the vine and exposed to the sun. Netted and grooved melons, as a rule, attain their finest flavor in the house, and should be pulled as soon as the green color at the bottom of the grooves has fairly begun to lighten. If a netted melon is pulled a little too soon it will keep a long time but never ripen, and some varieties when apparently well matured will only go to decay if separated from the vine; such are not favorite sorts with the trucker, but may be improved by hybridization with such as ripen more readily.

Cold nights, cold, damp ground and a mild temperature, with very little or too much rain, are all antagonistic to the growth and maturing of our Cantaloupes. Cold ground, with in the day a moderately warm sun, will cause a large melon to grow flat at the bottom and very convex at the top; the flesh of the upper part will also be much thicker and better flavored than that of the bottom. This rule of flavor is a general one, and a generous way to divide a melon is to cut it through the middle of the ground spot, either crosswise or through the stem and flower ends. In seasons like that of last year, melons only become about half netted for want of sun, and are poor in flavor when considered ripe; vast quantities brought to market never ripened. The melons from my Armenian seeds were exceptional in being densely netted.

Although the pollen of a Cucumber flower is capable of ruining the flavor of a Cantaloupe, it is very rare for a hybrid to be produced. I have seen such, between a Cucumber and a Jenny Lind melon, which was a decided curiosity. A noted Palestine Cucumber, known as the Mukte's, is produced upon a vine that very closely resembles in leaf and color that of a Cantaloupe; still, the fruit is an old variety of Cucumber and quite distinct from any of our sorts. The long Banana Cantaloupe makes a curious hybrid with the Jenny Lind, the product being oval, yellow, almost free from netting, very fragrant and salmon-fleshed; it has a better flavor than the former, but is quite inferior to the latter.

In Armenia there grows a Cantaloupe, probably of large size, to judge by the seeds, which is so sensitive to the heat of the sun that the gardeners are in the habit of covering the young melons with earth until they reach a certain size, when they are uncovered; this variety will be tested the coming season in several localities. The seeds are very large and white, much larger than any we have, and resemble those of the curious yellow Cappadocia melon introduced by me several years ago and not now grown; it was long, flat, smooth and salmon-red fleshed, like the Banana Cantaloupe in all points except in its shape.

Some years ago a few winter Cantaloupes were grown in this latitude, but the measure of success did not encourage the grower to continue the experiment; still, I see no reason why other attempts should not be made. American visitors to Naples are willing to pay sixty cents for a green melon in winter, and speak of it as wonderfully fine; in fact, it is the finest Neapolitan variety, and ought to be grown in some southern state, if possible, as a new industry. If the Naples melon will not succeed, the Malta green one should be tried. These melons are put away in the fall before they begin to ripen, and kept in a cool place. When one is to be ripened it is hung up in the open air in a warm place, in a net or a little bundle of straw, as bottles are sometimes encased for packing. The Naples seeds are very large, but of a form that ought to grow; the dry soil varieties may do better in our country. —*From an Address before the Pennsylvania Horticultural Society, by Dr. Robert P. Harris.*

Orchard Experiences.—III.

THE relative value of the different methods of propagating fruit-trees is frequently discussed, but often from a too narrow and local experience. In southern Maine, for instance, nearly all the fruit-growing farmers habitually denounce root-grafted and low budded trees as worthless; and "New York trees," even from the best nurseries, are looked upon as frauds all over northern New England. It is needless to say that this is unjust; but the feeling, nevertheless, exists, is very wide spread, and has its basis on what is supposed to be a general experience.

The approved method of propagating Apple-trees in southern Maine is to grow seedlings in a nursery up to four or five years, to select the most thrifty for planting in the orchard, to set them out, and three or four years later top-work them, by grafting or budding in the limbs. This produces a tree that satisfies the requirements of that region; and the same process is in vogue in all southern New England, though low worked trees are not much objected to in Massachusetts, Connecticut or Rhode Island.

In northern New England and the eastern provinces of Canada the case is again quite different. Here experience has shown that not one Apple-seedling in a hundred, grown from seeds of fruit brought from lower New England, will survive the test winters. In these sections root-grafted or very low budded trees have exclusive preference, upon quite as solid grounds of experience as top worked trees in southern Maine. If top working is ever successful in the "cold north," it must be a double working—the stocks being first root grafted or low budded to some "iron-clad" variety and then reworked in the branches after they have been established in the orchard.

It may appear strange that such diverse views should prevail over what may seem not a very wide extent of country. This extent is greater, however, than many suppose—the extreme distance between the St. Lawrence River and Long Island Sound covering between seven and eight degrees of latitude, with a difference in winter climate as great as that between New Jersey and South Carolina.

In the Apple-growing region of Maine, extending but little more than fifty miles back from the sea-coast, Apple-seed-

and the ill repute of "New York trees" is due, not to the way in which they are worked, but to the tenderness of the varieties offered. Root grafted or low budded Oldenburghs, Wealthys, etc., succeed well; and were it not for the misrepresentations or the ignorance of those nurserymen who are sending out such insufficiently hardy kinds as Mann, Pewaukee or Wolf River, root grafted trees of the "iron clad" varieties would find a large market there. In fact, considerable quantities of New York grown Oldenburghs, Tetofskys, Wealthys, Scott's Winters and Yellow Transparents are now sold there, although the dealers, well aware of the old and strong prejudice, declare them to be home grown.

As all this ignorance, and consequent prejudice, is injurious, alike to the growers and planters of trees, it well behooves all those of the former class to inform themselves thoroughly about the hardiness of every variety they grow. As their location deprives them of practical experience on the subject, they ought to study the reports of the local horticultural and pomological societies. There is a rich mine of knowledge to be found in the reports of Iowa, Minnesota, Wisconsin, Onta-

Fig. 28.—The Cypress of Montezuma.—See page 150.

lings from home grown seed are usually hardy enough to be used in the orchard for top-working successfully such varieties as the Baldwin, Rhode Island Greening, Northern Spy and Roxbury Russet, which are the leading commercial Apples of that section. Not one of these Apples, nor of such fall varieties as Gravenstein and Porter, are hardy enough, except quite near the coast of western Maine, to endure the climate when worked low. So grown, the young trees suffer in the trunk from the hard winters, and become unsound and unprofitable in a very few years. This explains why "New York trees" have so bad a name there; and the same is the case with the strip of country of about equal width, extending west from Maine to Lake Champlain.

South of this belt, in southern New Hampshire and Vermont and in the three lower states, low worked trees are again available. The only other section where the conditions of southern Maine are encountered is in the upper Champlain Valley. Here, again, the great commercial Apples named must be top worked to be enduring; but elsewhere in northern New England and in the provinces a climate is reached in which not even top-worked Baldwins, Greenings, etc., can endure the winters. Here an entirely different class of Apples is called for,

rio, Quebec and Maine; and every commercial orchardist in those sections, as well as every nurseryman desirous to supply the "cold north" with trees of a quality that will enable them to hold their trade, has need of it. It is quite as necessary to know what will not, as what will answer to plant in every county where a sale is sought. There are no better trees than those grown in the New York nurseries, but a sort of supercilious attitude in a few of them stands in direct antagonism to their own interests as well as to those of their patrons.

Newport, Vt.

T. H. Hoskins.

Notes on Hardy Ferns.

Asplenium Filix-femina is one of our most common northern Ferns, and one of the easiest to transplant. It varies much according to the location. In rich soil, along the margins of swamps, it is frequently over three feet high, with fronds nearly a foot wide; while in other localities, and in poor soil, it is often only eight or ten inches high, with fronds proportionately narrow. These forms are all very beautiful, and seem to thrive in moist soil in either sun or shade. The variety *angustum* of this species has narrow, erect fronds, though often two feet

high. It is quite distinct in outline from the common type and much rarer.

Another Spleenwort, a more local plant, is *A. angustifolium*, although, in its chosen home, it is usually abundant enough. It seems to select moist, half shaded ravines. The fronds, unlike most of our hardy Ferns, are only once divided. Those which bear the fruit are narrower and generally taller. In the tallest specimens the fronds are about three feet long, of a light green color, and generally three inches wide. It thrives in moist, loamy soil, and prefers some shade. Like most hardy Ferns, it needs time to become established; and plants are generally stronger and finer the second year after setting.

Asplenium ebeneum is a much smaller species than either of those above mentioned. It is seldom more than a foot high, with fronds an inch wide, once divided, and with a black and shiny stem. The fronds are evergreen. It is found on broken, rocky terraces, in the sun or half shaded situations, in crevices of broken rocks. It is, therefore, a rather local plant, though not rare. We have always found it hardy enough, and it surely thrives naturally in exposed situations. It should be valuable in many parts of the rockery on account of its size and shape. Usually, in the larger specimens, the fertile fronds stand erect, with a tuft of smaller sterile ones prostrate about the roots.

Of the Shield Fern (*Aspidium*) we have in New England about fourteen species and varieties. One of the most common and valuable for ornamental purposes is *A. acrostichoides*. This species, which bears a once divided dark evergreen frond, is inclined to grow in clumps, and fine plants can be grown in either sun or shade. The variety *incisum* is not common, nor do we believe perfectly fixed in character. It is not rare to find plants with some fronds deeply incised, while others are almost or quite free from this. The fronds of this species are thick and durable, usually appearing nearly as fresh in early spring as in autumn.

The Climbing Fern (*Lygodium palmatum*), when once established, is one of the most charming species we have. It seems to transplant best in the spring. Naturally, it grows among low shrubbery, seldom or ever in the open sun, but twining over low bushes, which shade its roots. A moist, loamy soil is needed, with a low trellis to support the slender, twining stalks.

Southwick, Mass.

F. N. Horsford.

Anthuriums.

THIS highly ornamental genus of tropical plants may be divided into two classes, (1) those varieties characterized by their handsome foliage and (2) those in which the flowers form the most noticeable feature. The members of the latter division have been comparatively few in number, at least in original types, the larger part of the fine-flowered Anthuriums having been of garden origin. The most widely known of the original species is *A. Scherzerianum*, the oblong-lanceolate leaves and bright scarlet spathes of which are familiar to all gardeners. This plant has greatly improved under cultivation, and has produced a number of varieties, as the seedlings vary greatly both in form and size of flowers and foliage. Among the most notable of these are *A. Wardii*, a very large and strong-growing form, both foliage and spathes being particularly broad, and the latter very brilliant in color; *A. Cypheri*, the spathes of which are inclined to crimson in shade; and *A. Rothschildianum*, the last named having bright scarlet spathes, which are usually dotted or marked with white, and it is especially recommended by some growers for its free-flowering qualities.

Anthurium Andreanum is another species in the flowering section, now becoming widely distributed, as it seeds profusely and the seeds germinate readily in a warm house and moist atmosphere. This, like *A. Scherzerianum*, is quite variable when raised from seeds, and some forms thus produced will be found of little value, while others from the same sowing may prove of special merit. *A. Andreanum* is of stronger growth than *A. Scherzerianum*, and in some cases it assumes an almost scandent habit, in which, however, it should not be encouraged, as the flowers are apt to depreciate in quality when the stem of the plant becomes long and straggling.

A. Ferrierense is very much like the last named species in growth and habit, the chief distinction being in the color of the spathe, which is a deep, rosy pink. This variety is not so much of an acquisition as *A. Andreanum*, and has not become a general favorite.

In the other section of the Anthuriums are to be found some with leaves so large and beautifully marked that they are among the choicest ornaments of the tropical house.

Prominent in this class is *A. crystallinum*, an extremely handsome plant from tropical America, with very large cordate leaves, the veins of which are marked out by bands of white which remind one of frosted silver.

Somewhat similar in general appearance is *A. magnificum*, a noble species with leaves from two to three feet in length and broad in proportion. The ground color of the leaves is dark olive-green, which offers an admirable contrast for the white veins, and makes this plant one of the most effective for exhibition in a collection of foliage plants. *A. Warocqueanum* is a species of more recent introduction than the preceding, and is well worthy of a place in any good collection. This plant has large cordate-acuminate leaves of bright green, with prominent veins of a lighter shade.

Another handsome plant from South America is *A. regale*, the leaves of which are a rather dull green in color, with white veins, and stand up well on long foot-stalks. *A. regale* is also a strong grower, and if properly treated will produce its large and striking foliage quite rapidly.

As regards soil, all of the Anthuriums require a light, rough compost, a good mixture being equal parts of fibrous peat and chopped sphagnum, with a liberal addition of clean, sharp sand, and some broken charcoal. The drainage of the pots or pans should also be properly attended to by filling them with crocks or other suitable material, for while they enjoy copious waterings during active growth, the Anthuriums are liable to suffer if the soil should become sodden and sour, and the thick, fleshy roots soon rot. They need a warm temperature, sixty-five to seventy degrees at night being most suitable for the species with ornamental foliage, though *A. Scherzerianum* may be grown in a lower temperature successfully. Shading will be found necessary during the summer months, and a moist atmosphere at all times, and in the case of those grown especially for their foliage it is best to remove the flowers as they appear, not only on account of their insignificant appearance, but also to prevent their weakening the plant. Seeds may be sown in a mixture similar to that recommended for potting, and if placed on brick bottom-heat and kept moist, it will germinate in a few weeks. They are best sown as soon as ripe.

Holmesburg, Pa.

W. H. Taplin.

The Spring Garden.

TWO snow-falls within the last fortnight protected low growing plants through a few days of low temperature, and flowers which were in bloom at the time passed uninjured through what to most people seems a severe trial. Really, however, a blanket of snow is the best possible protection from cold winds and biting frosts, and melting snows seem to stimulate the growth of early growing plants. Is this because of the ammonia contained in snow-water? Many of these plants are alpine, and in their natural stations they flourish close to the edges of the snow-banks as they retreat before the warm, bright sun. Of course any stimulus in the snow water is a minor element compared with the effect of the increasing heat of the sun, the manifestation of which in the annual renewal of growth in the spring is one of the most imposing displays of natural forces. With the increasing light and warmth almost all of the early blooming plants are boldly blooming or rapidly preparing to do so. I noticed this morning that one little Squill, which for weeks had peeped at the level of the ground apparently watching its opportunity, had at last suddenly thrown its bright flowers gaily to their full height. Not so bright, but earlier to bloom than any of the Scillas, is a little Grape Hyacinth from Mount Taurus. This is especially good for the rockery, as the plant is rather diminutive and its color (blue) rather dark in tone for effect on the level. It sends forth its long, narrow foliage in the fall and has been one of the earliest flowers to show color, and yet it opened very slowly. While it has not been injured in any way by frost it seems rather discouraged in bad weather. The flowering scape is only some three inches high.

More cheerful are the Primroses, on which straggling blooms have appeared all winter, though the hybrid varieties, such as we usually grow in the garden, do not pass unscathed either in flower or foliage during severe weather. However, we seldom have bloom until April, and while the foliage may be scorched by frost new leaves are quickly put forth. The plants are perfectly hardy and most accommodating subjects, as they bear shifting without injury, and, provided the clumps are not broken up just before blooming-time, will always give a good crop of flowers. In heavy soil Primroses grow vigorously and I prefer to leave them without protection, as wet is a greater enemy than severe weather. Primulas in bloom are surely among the most pleasing flowers and indispensable in spring

gardening. A stock is easily prepared, as seeds of a good strain (Dean's is as good as any) if sown in April or May will make strong plants before winter, and will bloom the next spring. After blooming they may be separated into single crowns and planted in odd spaces to make growth for another season. Flowers of a good strain, in color white, yellow and many intermediate shades, are an inch or more in diameter, larger than *Polyanthus* (*P. elatior*) and preferable in many respects. In fact, the average cultivator will find the modern hybrid hardy *Primulas* quite sufficient for his wants in this family, for while there are some fine "species" a large number are of interest principally to the specialist. Where protection of a frame can be had *P. cortusoides* will be found satisfactory, as it has been much improved in recent years by careful selection. This is a deciduous species, and it is now starting into new growth, the foliage having disappeared in the fall. A frame suitable for alpine *Auriculas* seems to suit it.

Elizabeth, N. J.

J. N. Gerard.

Orchid Notes.

Cymbidium eburneum.—Many plants of this desirable Orchid are now in full flower with us, filling the house with their delightful perfume. Even when out of bloom this Orchid, with its finely arching, dark green grassy foliage, is highly ornamental, and the wonder is that it is not more commonly grown. The scapes, which are erect and clothed with large green bracts, bear one or two flowers about five inches across; these are ivory white, of good substance, with a large blotch of orange-yellow on the front of the lip, and numerous spots of crimson on the under surface of the column. *C. eburneum* grows freely in an intermediate temperature if abundance of air can be given. At no time should the plants be allowed to become dry. When not overpotted scarcely too much water can be given. The pots should be well drained, and the soil should consist of two parts of rich fibrous loam to one of well rotted manure, with plenty of sand to keep it open. The thick fleshy roots are great feeders, and as soon as they fill the pots liquid manure should be given two or three times a week. There are two or three named varieties of this species, but none of them are particularly distinct. It was introduced from the East Indies in 1846.

Chysis Chelsonii.—This magnificent hybrid is the result of crossing *C. bractescens* with *C. aurea*, but it is far superior to either of its parents and in every way more vigorous. On strong plants the bulbs are more than eighteen inches long and three inches in diameter at thickest part. The upper portion of the bulbs is clothed with the bases of the long lanceolate leaves. The racemes which appear with the young growth are about one foot long and bear about a dozen handsome flowers of fleshy texture and about three inches across. These are of a nankeen color, with the apex of the segments orange-red. The lip is prettily streaked with red, and the flower lasts a long time. *C. Chelsonii* should be grown in the warmest house, potted in a compost of sandy peat and loam, with a liberal addition of chopped moss and rotten leaves. Abundance of water should be given after the new growth is well rooted with occasional doses of liquid manure. After the growth is fully matured water should be to a considerable extent withheld, and the plant removed to a drier atmosphere.

Lycaste gigantea, as its name implies, is of unusually large growth. The stout, conical bulbs are about six inches high, and surmounted by two or three thin, lanceolate leaves more than two feet long. The scapes, usually five or six in number, appear from the base of the bulb, and with the new growth. They are erect, nearly eighteen inches long and bear a single flower more than eight inches in diameter; the lanceolate acute petals and sepals are yellowish green. The lip is fleshy, purplish brown, beautifully margined and fringed with orange. The large, pure white column is densely clothed with short hairs on the under surface. *L. gigantea* succeeds admirably in a mixture of peat and moss, with a liberal addition of chopped, half rotten leaves. It requires an abundance of water during growth and should at no time be kept dry. It does best with us in the intermediate house—that is, in a temperature of fifty-five to sixty degrees during the winter months, and as cool as possible in summer, with abundance of air. This species was introduced from Central America in 1843, but is not often noted in collections.

Lycaste cruenta, now flowering freely, is of quite a different type from the foregoing. It is deciduous, losing its leaves in early winter, and consequently it should be kept fairly dry in a cool house until the new growths appear. The numerous scapes are about six inches long, bearing a single flower about three inches in diameter. The sepals are greenish yellow, the petals and lip deep orange, excepting a large blotch of crimson

at the base of the latter and a few spots of the same color on the base of the former. This is a very free blooming plant, and the flowers—which are fragrant—last quite a long time in perfection and are very useful for cutting. It requires very liberal treatment during growth, but care should be taken not to overpot it.

Kenwood, N. Y.

F. Goldring.

Iris Susiana.—Of the numerous species of *Iris* now in cultivation, none are more beautiful than this. Exquisitely delicate is the penciling of the petals, the inner three of which, usually known as standards, are of such a size as to place this species among the largest of the genus, a well developed flower measuring seven inches across. The three outer and lower petals, or falls, are partly clothed with a dense beard, and have a dark brown blotch in the centre of each. This plant is by no means a new one, having been among those cultivated by Gerard and figured in his *Herbal* three centuries ago. *Iris Susiana* is a native of Mesopotamia and Syria, and it is unfortunately too seldom met with in flower under cultivation. This is probably because its peculiar habits and requirements are not sufficiently understood. *I. Iberica* much resembles *I. Susiana* in this respect, and both belong to a division of the sub-genus *Euiris*, known as *Oncocyclus*, so that their botanical and cultural affinity is well marked, and we find them both to succeed well under the same treatment. These *Irises* are usually imported in autumn in a dried state, together with other flower-roots, and when received they should be potted up in a sandy compost and placed in a cool house or frame, where they will commence to grow at once, and continue to do so through the winter until their flowering season, which is in early spring. They rarely flower, however, the first year. When the weather will permit the plants may be transferred to a well drained soil in the border. In June the leaves die down, and the plants rest until September. During this period of rest English growers place a hand-light over the plants to ripen them by artificial drought. This is not necessary here, owing to the greater amount of sun-heat to which they are naturally subjected. In September growth begins and continues throughout the winter if the plants be lifted in fall, potted and placed in a cool house; and then flowers may be expected in March. It must not be inferred from this that these *Irises* are not hardy, for we have flowered them in the open ground and expect to do so again. But when their beauty and the simplicity of their culture is considered, it is not too much to ask for them pot-room in a cool house, where they will present a welcome relief to the monotony of *Calceolarias* and *Cinerarias* in the spring months.

Passaic, N. J.

The Forest.

The Hemlock.

WITH the exception of the White Pine, the Hemlock must be regarded as the most valuable of all the trees of the United States east of the Mississippi River, so far as abundance of timber products up to the present time is concerned.

The wood, for many purposes, especially in the unexposed parts of structures, has no superior, if, indeed, it have any equal. Its capacity for holding nails is greater than that of the White Pine, while its durability is equally great in corresponding exposures. With these qualities in its favor, the Hemlock must be regarded as worthy of careful consideration with reference to its bearing upon the important forestal problems of the nation. In the brief paper I have prepared for the present occasion, I have drawn my matter largely from a report upon the Hemlock, prepared by me for the Forestry Division of the Department of Agriculture, based upon a somewhat extended study of its biology, history and economy.

The wide range of the Hemlock, covering, in its natural distribution, more than one-half million square miles, extending through thirty degrees of longitude and thirteen of latitude, would of itself suggest its adaptation to forestal purposes. The impression received from its distribution is further strengthened in the fact that the tree grows naturally in a considerable diversity of soil, climate and situation. Few trees of our native forest are more marked in this respect, and somewhere within its range it is found as an associate of nearly every species of the arboreal flora of eastern North America north of Alabama. If, however, we examine the question from the stand-point of actual experience in the cultivation of the Hemlock, the matter appears far less encouraging.

I.—The demands which the Hemlock makes in regard to soil and climate are of so general a nature that no obstacle to its cultivation can arise from this consideration, although, like other plants, it manifests a certain preference for particular

situations. Throughout the area covered by its natural distribution there are millions of acres adapted to the highest development of the Hemlock, which are unfit for any other than forestal purposes. No requirements exist, therefore, in regard to soil and climate, which are not amply supplied.

II.—The tendency of the Hemlock to renew itself naturally on areas which have been largely or completely deforested, is less marked than that of most other tree species. Still, the tendency to natural renewal is by no means wanting. The writer has seen a large pasture adjacent to a piece of Hemlock woods well stocked with a growth of young Hemlocks. They bore evidence of having been disturbed by cattle, but there were abundant indications that if left to themselves they would completely reforest the area on which they were growing. Other similar instances have been mentioned by correspondents in numerous locations. The Hemlock is an abundant bearer when once it has reached the fruiting age, although the seed-crops are biennial. The chances for a wide dispersal are enhanced by the structure and hygroscopic quality of the cone. The seeds are shed at different periods, extending from autumn until spring. Fertile seeds have been found in the cones as late as the last of April. The seeds, if favorably placed, germinate freely; the specially favoring conditions being a moderate amount of shade and moisture. The latitude, in this respect, is not great, as any considerable excess of moisture causes the young plants to damp off, while from any great lack of it they wither and perish. While the young plants must be regarded as exceedingly delicate, they are, nevertheless, capable of enduring a considerable range of climatic and other conditions. There seems to be no inherent reason in the nature and constitution of the Hemlock to operate against its natural renewal on areas from which it has been removed, provided the conditions are favorable to that end. The essential conditions are twofold: First, the rigid exclusion of all domestic animals; second, obviously and chiefly, the prevention of forest fires. While these conditions apply to all tree species in common with the Hemlock, they are relatively of greater importance in regard to the latter on account of its constitutional delicacy. A third condition would be the removal of a certain proportion of the seedlings of other species which are endowed with a greater degree of vigor.

III.—In regard to the cultivation of Hemlock in nursery rows for subsequent transplanting, practical experience shows its want of adaptation to this purpose. In its seedling state it is probable that no other tree species is of so slow growth; at the end of its first year a seedling is rarely more than an inch in height; and at the end of its third or fourth year it has increased to scarcely more than three or four inches. This low growth is characteristic of the Hemlock during many subsequent years, although at a later period the relative rapidity of growth is somewhat increased. While these facts materially lessen the adaptability of the Hemlock to forestal purposes, they do not prevent the employment of the Hemlock in the renewal of forests in the method previously considered. Moreover, it should be stated that while the rate of growth here indicated is based upon my own experience and observation, and is confirmed by many correspondents who have had large experience in the cultivation of the Hemlock, there are a few correspondents who consider it to be, in specially favored situations, as rapid a grower as most other conifers.

IV.—A few facts concerning the consumption of the products of the Hemlock may be here noted. What are regarded as trustworthy estimates, place the amount of bark used for tanning purposes in 1887 at 1,200,000 tons, which, at eight dollars per ton, would represent a value of \$9,600,000. Estimating the amount of manufactured lumber at 1,500 feet per ton of bark, would give 1,800,000,000 feet as the total amount, representing a value, at twelve dollars per 1,000 feet, of \$21,600,000. While a considerable portion of the peeled timber is wasted, and should be deducted from the above estimates, it is believed this amount is made good by the use of unpeeled timber for railway ties, fuel and various other purposes. It may, therefore, be estimated that the full value of the products of the Hemlock is, in round numbers, \$30,000,000 per annum. The length of time during which our remaining Hemlock forests will continue with this annual

drain upon them is, of course, uncertain; but the most careful and conservative observers consider that the present supply could not be maintained for a period exceeding twenty or twenty-five years. It becomes, therefore, a question of great practical importance as to the way in which the existing demands upon the Hemlock shall be hereafter supplied. These supplies can, of course, be afforded in only two ways: First, by the substitution of corresponding products from other trees or other sources; Second, by the renewal of the Hemlock forests.

The general conclusions which have been arrived at as the result of a somewhat careful investigation of the present subject may be briefly summed up as follows: The Hemlock has been, from the earliest settlement of the country, a tree of vast economic importance to the people of the eastern and northern states; that in this respect it has been second to none of our native forest trees, with a possible exception of the White Pine; that the tree has been exhausted from vast areas where it formerly existed in great abundance; that at the present rate of consumption the entire supply will be practically exhausted in from twenty to thirty years; that nothing has been anywhere done toward reforesting the areas from which it has been removed, and that its nature and constitution afford only a moderate promise of its adaptation to economic forestal purposes. Finally, it may be stated that the most prominent result of the investigation to which I have referred has been to give great emphasis to the fact, not as yet sufficiently recognized, that the country ought to give prompt and energetic attention to the whole subject of forestry, that no successful forestal management is possible in the absence of adequate knowledge of the subject, and that this knowledge is attainable only through intelligent experiment, experience and study.—Read before the American Forestry Association by Professor A. N. Prentiss.

Correspondence.

Hollyhock Diseases.

To the Editor of GARDEN AND FOREST:

Sir.—So much has been said about the true Hollyhock disease (*Puccinia malvacearum*, Mont.) that it is only fair to call attention to another one. Last year, in and around New Brunswick, New Jersey, it was almost impossible to find a single healthy Hollyhock among the thousands of plants. At first the lower leaves began to exhibit large circular brown patches, sometimes bounded upon the side toward the centre of the leaf by the veins, thus giving an angular outline. Soon after the largest leaves of all suffered and fell, and by the middle of August whole rows of the plants exhibited leafless stems. Few gardeners now have any plants, but one enterprising propagator has a long row of fair-sized seedlings in pots. When I first saw these seedlings they were—a few hundred of them—in a box under sash, and so badly infected with the blight that there seemed at first to be no hope for them. Perhaps one plant in five was saved and pricked out in a fresh box; and the following remedy was applied almost daily: Three ounces of carbonate of copper were dissolved in a quart of standard ammonia, and afterward diluted to twenty-two gallons with water. At the same time the older leaves which developed the spots were removed and burned, until a comparatively healthy condition has been reached. The disease is due to a *Cercospora* and probably *C. althaina*, Sacc., a species which in its various forms grows upon the common Mallow (*Malva rotundifolia*), Velvet-leaf (*Abutilon Avicennæ*) and a species of Callirhoe.

As said in the beginning, too much credit should not be given to the Hollyhock rust (*P. malvacearum*) that has come to us from abroad while we have a blight of our own to attend to, even if it is one that can be kept in check perhaps if taken in time by using a compound of copper.

Rutgers College.

Byron D. Halsted.

Grafting.

To the Editor of GARDEN AND FOREST:

Sir.—I do not think Mr. Parsons goes quite to the bottom of this question of grafting (see p. 44). My view of the question is that if any conifer will not grow in America or in Europe without grafting, it is not worth cultivation at all. Grafting for timber-trees will never pay. The plain fact is that own-rooted fruit-trees have never, or very, very rarely, been tried side by side with the grafted ones, and until this is done no one really can know that grafting is the best, or even one of the best ways. One would have thought that our horticultural societies, or those botanists who profess to know something of vegetable

Fig. 29. — Seedling Hemlocks, one and three years old, natural size.

physiology, would have settled this simple question of grafting, or of stocks versus own roots, long ago. But not a bit of it; in point of fact, the scientific people do not know as much as the practical gardener in this matter, and even the gardener is too often led by custom, or he does what is usual, rather than undertake original research for himself. Knight long ago formulated the axiom that the best form of vegetative restriction or pruning to which a fruit-tree could be subjected was a heavy crop of fruit.

It has been well said that every red deer shot in Britain costs at least fifty pounds, every pheasant at least a guinea; and in many private gardens the peaches are not grown for less than five shillings apiece! I lately saw some Peach-trees as grafted on Plum stocks. They are half-standards in a vinery and the Peach scion is vainly protesting against starvation by trying to root out all around the swollen point of the so-called "union" between scion and stock! The Peach-tree on its own roots grows as freely as a Willow, and if any restriction is wanted we have half a dozen ways at least, each and all more efficient than grafting.

Grafting has become a sort of fetish with many propagators. Nature at her best is ahead of even the most successful gardener, and she does not graft her productions. The Grapes of Alicante or Cashmere are not grafted, and I have yet to learn that they have been surpassed in our gardens. So also the Peaches of Persia and the Apricots of Thibet, of which travelers rave when eating the finest grafted produce of the west. That finest in flavor of all Pears, the American Seckel, was a chance seedling and not grafted, and I have never heard of a grafted tree that could surpass the original one as discovered by "Dutch Jacob" near the Delaware. The original tree of the Ribston Pippin Apple was an ungrafted seedling, and a root-sucker from it is alive to-day, but I do not know of any grafted fruit-tree in Britain a century old, and for every thousand of grafted conifers alive, and very often stunted and unhappy, in Britain to-day, there is reliable evidence to prove that at least ten times that number have proved to be disappointing failures.

Botanical Gardens, Trinity College, Dublin.

F. W. Burbidge.

Grafting Oaks.

To the Editor of GARDEN AND FOREST:

Sir.—It has always been thought that the grafting of American Oaks on stock of European species, a difficult operation to perform in some respects, could not make long-lived trees and that this was especially true of *Quercus coccinea* and *Q. rubra*. Moreover, as the acorns of several varieties have been imported in quantity during the past century, it was easy and natural to secure them, and therefore but little grafting was done. I have noted a remarkable exception to this, however, near Potsdam, the Prussian Versailles. The marble palace stands on the borders of a lake in which are mirrored masses of foliage from the surrounding trees in a beautiful park still called "The New Garden," although it is now a hundred years old. Laid out at a time when the interest in American trees, then newly introduced, was at its height, this royal garden is rich in foreign varieties of forest trees, which are now in fine condition, as perhaps will be remembered by you and Mr. C. A. Dana, with whom it was my good fortune to visit this spot. Near the library, standing apart from other trees, there is to be found a remarkably fine specimen of *Q. rubra*, grafted upon our *Q. Robur*, for which our name is Steineiche. This interesting tree is thirty-three feet in height, with a circumference of six feet seven inches. The graft was made at the height of thirteen feet, and what makes the appearance of the tree peculiar in winter is the fact not only that the bark of the top is much smoother than that of the trunk below, but because the top is entirely leafless, while at the same time the branches which have been put forth below the graft still hold their leaves, though browned and shriveled by the winter.

M. Reuter, head gardener at Peacock Island, first called my attention to this tree. The establishment of this park at Potsdam dates back just a century, that is, from the commencement of the short and brilliant reign of Frederic William II., the successor of the great Frederic. If, as is reasonable to suppose, this tree was among the earliest planted, its age must be estimated at from 90 to 100 years. In this case the durability of the graft could not be better demonstrated.

Berlin.

C. Bolle.

The Study of Botany.

To the Editor of GARDEN AND FOREST:

Sir.—I am glad you advocate the study of botany for the young, as it gives them an interest in natural objects which may be a source of pleasure to them through life.

Perhaps my experience with my own little girl may interest you. Three years ago, when she was nine, I made up a class of children of about her age, and engaged a botanist to give them lessons twice a week during the summer. These lessons were much enjoyed by the children, who always looked forward to them with pleasure. The interest which they took in flowers was greatly increased, and this added much to the pleasure of their walks. Their powers of observation and discrimination were increased, and the technical names did not seem to present any difficulties.

We spent last summer in Switzerland, where the vegetation was a constant source of pleasure to the children, so that the journeys, which are apt to be tiresome to young persons, were made delightful to them, by their finding and collecting flowers.

This winter, of their own accord, they have taken up the study of mineralogy, which interests them as much as botany.

It seems to me that the study of the natural sciences is better fitted for the education of young children than most of the branches taught in schools. One great advantage they certainly have; the children become fond of study and investigation, their education becomes a pleasure, and their faculties are more evenly developed than by those studies which exercise little besides the memory.

Highland Falls, N. Y.

P.

Orchids at Easton, Pennsylvania.

To the Editor of GARDEN AND FOREST:

Sir.—Early last month I paid a visit to the greenhouses of J. Eyerman, Esq., College Hill, Easton, Pennsylvania, where almost always there may be seen a number of choice Orchids in bloom. Phalænopses in five varieties were finely in flower, including a beautiful dark rose colored and well shaped *P. Sanderiana*, but noticeable above all was a magnificent and substantial variety of *P. grandiflora*—the old Java form. The spike carried six enormous and very compact blooms, measuring more than four inches from petal to petal and three and three-fourths inches in depth. This may be considered a gem amongst Phalænopses.

The genus *Cypripedium* finds special favor in the eyes of Mr. Eyerman, and there may be seen in flower and bud the following kinds: *C. Boxalli*, *C. villosum*, *C. Harrisianum*, *C. nitens*, *C. Lowii*, a fine variety of *C. plumerum*, several specimens of *C. Argus*, including one extra-broad petaled and highly colored form; *C. hirsutissimum*, *C. cardinale*, *C. callosum*, *C. bellatulum*, *C. Parishii*, *C. grande*, *C. Dayanum*, *C. Danthieri*, *C. chloroneurum*, *C. caudatum*, *C. Crossianum* and numerous plants of *C. Lawrenceanum*.

Cattleyas and Dendrobiums, in great variety, were in bloom with *Lycaste Skinneri*, including a fine plant of the always rare and lovely variety, Alba, bearing six flowers, a grand specimen of *Cymbidium Lowianum*, several of *Cymbidium eburneum*, and the attractive *Lælia harpophylla*. Odontoglossums and Oncidiums of many kinds were flowering well, and last, but not least, I noted a handsome plant of the deliciously fragrant little Orchid, *Dendrochilum glumaceum*, with some seventy spikes of flowers.

New York.

E. V. L.

Notes.

The international botanico-geographical exhibition which was to have been held at Antwerp during the coming summer has been postponed until 1891.

Thirty-three pages of the last number of the *Kew Bulletin*, in double columns, are taken up with a list of hardy herbaceous plants, shrubs and trees, the seeds of which may be had by way of exchange from the Royal Gardens at Kew.

In an article on "The History of Garden Vegetables," published by Dr. E. L. Sturtevant in the *American Naturalist*, he includes the Nightshade (*Solanum nigrum*), saying that "in the Mississippi Valley the little black berries are made into pies and other pastry."

The last report of the Park and Garden Department of the city government of Berlin shows that during the past year \$84,473 had been expended upon the nurseries and forest-plantations where material is grown for use in the streets and parks of the town.

Mr. A. L. Kean, writing in the *Botanical Gazette*, states that, from experiments made by himself, he believes the disease which since 1885 has seriously affected the Lily plantations of Bermuda is due to the same species of Botrytis which has afflicted *Lilium candidum* in England.

At a recent meeting of the Royal Horticultural Society in London a plant of *Masdevallia Tovarensis* was exhibited which bore 255 leaves and 162 flower-spikes with 346 open blossoms. When the exhibitor, Mr. Hodgson, bought the plant fifteen years ago it bore only two small leaves.

It appears from a London letter in *The Sun* that Madagascar has gone into the lumber business. The first cargo from that country reached England a fortnight ago, and the wood made a favorable impression on experts. It consisted entirely of hard woods, which resembled mahogany, walnut and teak, and commanded good prices.

Phalenopsis Cynthia × is recently described as a new natural hybrid affined to *P. leucorrhoda*, also supposed to be a natural hybrid. The only difference between the two is that the tendril-like appendages to the labellum are only about half as long in the former as in the latter, and in *P. Cynthia* there is a slight tinge of yellow on the front lobe of the lip.

The fruit-growers of southern California have found that a crop of Peanuts can be raised between the trees of a young orchard with no loss to the trees if the vines are left to decompose in the soil. The Peanuts net from five to eight cents a pound, which means from \$125 to \$200 an acre. This makes a good revenue from the land until the fruit-trees come into bearing.

The Sugar-cane disease which started three or four years ago in plantations near Cheribon, Java, is said to be spreading with alarming rapidity. At a recent congress of planters and others interested in the production of sugar, a fund of \$90,000 was subscribed to engage a bacteriologist to come from Europe, investigate the cause of this disease, and if possible devise a remedy.

A San Diego paper announces that an "herb garden" of some ten acres in extent is to be established near that city by Mr. Augustus Lang. Plants particularly valuable for their medicinal qualities, and, perhaps, flowers especially desirable for their perfume, are to be cultivated. A laboratory is to be erected for the treatment of the herbs and flowers grown, so that essential oils and extracts, as well as dried herbs, will be prepared for the drug market.

It is computed that 100,000 trees have been planted in the streets of Paris, exclusive of those which adorn the larger squares and parks. The kinds chiefly used are the Ailanthus, the Norway and the Sycamore Maple, the Horse-chestnut, the Elm, the Locust, the Occidental Plane (Buttonwood), the Silver Linden and the Paulownia. Such care is taken to provide a sufficiency of good soil that the cost of setting out a single tree reaches \$61, and \$50,000 are annually expended for the purpose.

Mr. S. E. Jelliffe has caused to be reprinted in separate shape the catalogue of the plants growing in Prospect Park, Brooklyn, which he originally published in the *Brooklyn Daily Eagle Almanac*. It includes, of course, many foreign as well as native plants, and the list embraces 286 flowering plants and sixty-two cryptogams. Among the latter one would, perhaps, have expected to find more than nine species of Ferns. It will be a pity if this list is not placed on sale somewhere in the park, and the example set by its author might advantageously be imitated by students in this and other cities.

Some analyses of apples, made at different periods of their growth, under direction of Mr. J. W. Clark, horticulturist of the Missouri Experiment Station, shows that much the greater proportion of the ash, or material drawn from the soil, is stored up in the early part of the growth of the fruit. This gives an additional reason for thinning early, or as soon as wormy or imperfect specimens can be distinguished. It shows, also, that a barrel of large and perfect apples takes a smaller amount of mineral plant-food from the soil than a barrel of small, inferior fruit. The analysis shows that the apples on an acre of ground, where the trees stand thirty feet apart, and yield ten bushels of fruit to the tree, take from the soil more than seven pounds of phosphoric acid and forty-three pounds of potash. This justifies the use of bone-dust and ashes, or one of the potash salts, as a dressing for orchards.

Writing in the March *Bulletin of the Torrey Botanical Club* with regard to a collection of Sedges sent him from Phoenix, Keweenaw County, Michigan (a spot on the western side of a small peninsula which juts into Lake Superior from the southward), Professor L. H. Bailey says that in all regions adjacent to the Great Lakes the flora is anomalous. "It presents a curious mixture of northern and southern types, yet the northern types are not particularly marked." There is "a tendency of the southern types to creep northward along the Great

Lakes, particularly on the shores opposite the direction of the prevailing winds. These winds, traversing the warmer area of the water, maintain the winter temperature on the shores upon which they blow at a higher point than it reaches on the opposite side. Thus it appears to be true that the flora of the eastern shore of Lake Michigan has in it more plants of a southern type than the western shore; at any rate, it is true that the western shore of the state of Michigan presents in its flora a warmer cast than does the eastern shore of the state." The most interesting entry in the list of sixty-four Carices is *C. exilis*, for which the most western locality hitherto known has been Wayne County, western New York, and which, even in the east, is a rare species.

A picture of the Washington Memorial Arch as it is to be built in marble, which was recently given in the *Sun*, shows many changes from the much admired wooden prototype. The piers are much more massive and the span of the arch relatively smaller, while the distribution of the ornamental motives is also quite different. Of course, the proportions suitable for a wooden construction could not have been exactly adhered to, and we may trust its designer to believe that greater beauty will spring from his modifications as well as greater stability. It was first proposed to place the arch in a line with the external boundary of Washington Square, but it has been decided to set it back half way between this point and the open central space. In this way the large trees near the street will not need to be removed, and, moreover, a dignified approach to the arch can be made by forming an open space in front of it with, it is suggested, a pair of isolated ornamental shafts bearing appropriate emblems. Some such treatment is certainly desirable if there is to be true harmony between the stately memorial and its surroundings. The sum raised for building it now amounts to \$75,000, but \$150,000 ought to be raised if the architectural beauty of the work is to be properly enhanced by sculptured decoration.

A correspondent of *The Garden*, London, gives some interesting notes on synonyms among Chrysanthemums. For instance, in 1886 Messrs. Cannell exhibited several new varieties imported direct from Japan, and which they distributed the following year. Among those which received a first-class certificate, and which was indeed quoted at a higher price than any other, was Mrs. H. Cannell, with beautiful pure white flowers. Now, this is by all growers (Messrs. Cannell included) regarded as synonymous with Christmas Eve, a variety distributed by the American nurserymen, and sent to this country two years previous to the distribution of the other, viz., in 1885. Another flower is Lady Trevor Lawrence, which is the same as Mrs. Beale and Robert Bottomley, this last coming from the other side of the Atlantic. Several other instances are recorded in different catalogues of the same variety being distributed by an English and an American nurseryman under different names. Included among the number are Mr. Frank Thompson and W. G. Drover, Marvel and Mr. H. Wellam, Charlie Sharman and W. M. Singerly, Mrs. Vannamann and Mr. Addison, with Mrs. J. N. Gerard and Mrs. Dunnett. All this is, no doubt, to be accounted for by the fact that they have been imported direct from Japan, and, therefore, the identical varieties have been distributed on the two continents.

Catalogues Received.

The Sugar Maple.

THE illustration on page 167 represents the Sugar Maple as this tree often appears when it stands in an isolated position on a New England hill-side. The subject of our illustration is in its prime, and shows the habit of the Sugar Maple at that period of its life when it has lost the rather narrow upright growth which often characterizes it during the first seventy-five years of its life and before it has taken on the broad-branched spreading habit certain individuals of this species assume in old age when soil conditions are specially favorable to their very best development.

The Sugar Maple is one of the finest of the deciduous-leaved trees of North America. It is by far the noblest of the American Maples, although the Silver Maple develops occasionally a greater trunk-girth, and it is perhaps the noblest of all the Maples, although the Sycamore Maple of Europe in the mountain valleys of the Tyrol is, when at its best, a tree second to none of its class in spread of branches and dignity of port. But the European Maple lacks the lightness and brightness of foliage and the gracefulness of inflorescence peculiar to the Sugar Maple, while it assumes in autumn none of the brilliant colors which our American tree takes on at that season of the year and which make it then the most conspicuous feature of the landscape wherever it abounds.

The Elm, to many people, is the characteristic tree of New England, because perhaps more than other trees it was selected by the early settlers to stand sentinel over their homesteads; but the Sugar Maple is hardly less characteristic of New England, and of all the Northern States, where it is almost everywhere a very common tree, growing on hill-sides and in valleys, and of late years so generally planted by the road-side that it is now more often seen than the Elm, which is a more fastidious tree than the Maple about its nourishment, more easily affected by drought, and a far more inviting prey to noxious insects.

The Sugar Maple economically is one of the most valuable American trees. The wood it produces is heavy and hard, close-grained, tough and strong. It has a surface which can be highly polished, so that it is an excellent and

much esteemed furniture wood, especially those peculiar forms with twisted and contorted grain known as birdseye maple. It is from the wood of this tree that American shoe-lasts are made in preference to that of any other, and it is used in the manufacture of hundreds of other objects, great and small, from the keel of a boat to a shoe-peg. The New Englander who wants to burn better fuel than that afforded by the Sugar Maple must use Hickory. The Indians knew the value of the sap of this tree and soon taught Europeans how to convert it into sugar. The production of Maple-sugar was once a far more important industry comparatively than it is now, although the crop is steadily increasing in bulk and in money value.

The Sugar Maple has one characteristic which very few American trees, except some of the Oaks, share with it to the same degree, and one which, when American forests are managed with the view of getting from them all they can be made to produce, will make it one of the trees most generally employed in the operations of scientific silviculture. It has the capacity to germinate and grow to a considerable size under the more or less dense shade of other trees. Young Sugar Maples form sometimes in the northern counties of this state, in northern Michigan and other parts of the country where this tree is common, the larger part of the undergrowth which has sprung up in the deciduous forests. These self-sown plants, in spite of the shade which, of course, checks their growth, grow with a good deal of vigor and reach a considerable height. The Beech in Europe possesses the same power of growing for many years under and among other trees, and it is for this reason that the Beech is one of the most valuable subjects in all European deciduous-forest operations looking to natural forest-succession—the prime motive of modern scientific forestry. The Sugar Maple is a far more valuable tree in the material which it produces than the European Beech, and American foresters, when we have them, will have good cause for congratulating themselves in the possession of a subject so valuable and so easily managed.

Our illustration is made from a photograph of a tree growing in a rocky pasture at Weed's Mills, in the town of North Sandwich, New Hampshire, at an elevation of a thousand feet above the sea-level. It was taken by Dr. Wm. Herbert Rollins, of Boston, to whom we are indebted for its use.

THE Governor of California has felt impelled to write a public letter to the Senators and Representatives of that state in relation to the criticism in the *Century Magazine* of the present supervision of the Yosemite Valley. It is to be hoped that the Commissioners have a more intelligent appreciation of their responsibilities than the Governor displays, for he makes it plain that he has not the remotest comprehension of the questions under discussion. Such an exhibition in an official of his rank is not an improving one, and yet it is hardly to be regretted that some of his personal allusions were so unjust as to compel Mr. Frederick Law Olmsted to make a formal statement which explains his early connection with the administration of the valley and his attitude in relation to the present criticism, for Mr. Olmsted takes occasion besides this to state some of the obligations of government when it assumes the duty of preserving natural scenery. After saying that the remonstrance in the *Century* points to nothing in the methods of the Commissioners that would be objectionable if the concern of the nation in the matter were of the same kind that it is with the state's dealings with mineral deposits, irrigation, schools, railroads or even forests, Mr. Olmsted adds:

"If the Governor and the Commissioners are in error, their error probably lies not in any intentional disregard of the state's obligation, but in overlooking the fact that in natural scenery that which is of essential value lies in conditions of a character not to be exactly described and made the subject of specific injunctions in an Act of Congress, and not to be perfectly discriminated without other wisdom than that which is gained in schools and colleges, counting-rooms and banks.

Such qualities as are attributed by the Governor to his Commissioners—integrity, general education, business experience and what is comprehensively called good taste—do not, in themselves, qualify men to guard against the waste of such essential value, much less do they fit them to devise with artistic refinement means for reconciling with its preservation, its development and its exhibition such requirements of convenience for multitudes of travelers as must be provided in the Yosemite. Whether it is the case with these Commissioners or not, there are thousands of such estimable men who have no more sense in this respect than children, and it must be said that those most wanting in it are those least conscious of the want. Men of the qualifications attributed to the Commissioners are the best sort of men for the proper duties of an auditing and controlling board. There could be no better men for the usual business of a board of hospital trustees, for example. But the best board of hospital trustees would commit what the law regards as a crime if they assumed the duties of physicians and nurses. Ability in a landscape *designer* is, in some small degree, a native endowment, but much more it is a matter of penetrative study, discipline, training and the development through practice of a special knack. Even men of unusually happy endowment and education, who have not, also, the results of considerable working experience, can rarely have much forecasting realization of the manner in which charm of scenery is to be affected by such operations as commonly pass under the name of 'improvements.'

In our view, this doctrine cannot be too strongly or too often insisted upon. If expert training is ever essential to the creditable performance of any work, it is needed in just such cases as this. No one but an artist in the truest sense of the word can select in a landscape the elements which fix its character, or estimate the relative importance of each in the distinctive charm which invests the whole. How to make this beauty available to visitors by artificial construction while preserving and developing in their due proportion these essential natural features is not a problem to be solved by journeymen.

We surrender more space than we usually devote to a single subject to the article below on "Sports," by Dr. Masters, the distinguished editor of the *Gardeners' Chronicle*. The subject is so important and its treatment so instructive and complete that our readers will no doubt prefer to have it entire and at once rather than in a continued form running through two or more numbers.

Sports.*

IT is highly desirable that we should attach a definite signification to this word. Among gardeners it may mean many things, whilst, among botanists, it is restricted to cases of bud-variation as distinguished from variation from seed. In this note we shall use the word in its botanical sense, as applying to a special illustration of that tendency to vary which is common to all living beings. We shall, however, gain a clearer idea of what true sports are by the elimination of certain things which are not sports, though often called so. In the first place they are not seedling variations. Out of a hundred seeds of Lawson's Cypress that are sown it is possible, I suppose, to get ten more or less distinct varieties, besides others which are more or less indistinct. The great variability of this species is now well known, and the seedlings of *Abies subalpina*, Engelmann (*A. lasiocarpa* of Hooker), furnish another illustration of the same tendency. These seedlings may be the result of cross-fertilization between varieties, or they may be reversions to an earlier condition; at any rate, of whatever nature they are, they are not "sports" in the sense here intended.

Next, sports are not mere stages of growth. Most plants put on a different appearance at various periods or stages of their growth, and sometimes these changes are very remarkable. The *Retinosporas* of our gardens furnish us with excellent illustrations. *Retinospora* (or more strictly *Thuya*) *pisi-*

fera exhibits during its growth very different appearances in its foliage. There is the squarrose form and the plumose form, the golden form, the silver form, the pendulous form, the thread-like form, the upright form, and perhaps others. All these, however, are not separate entities; they may all occur on the same bush. If cuttings or if grafts be taken they may be reproduced almost indefinitely.

Barring the mere color variation, these forms are but stages in the growth of the plant, occurring with more or less regularity and in greater or less degree of prominence in all the individuals of the species, as may be inferred from watching the growth of seedlings in a seed-bed.

Other illustrations of variations arising during growth are afforded by the differences often observable in the foliage on the flowering branches as contrasted with that on those branches which bear no flowers. The common Ivy furnishes an illustration. The short contracted shoots of the *Laburnum*, or the Apple, known as "fruit spurs," constitute other examples.

Another form of variation in flowers is that connected with difference of sex. A "pin-eyed" Primrose does not greatly differ in appearance from a "thrum-eyed" one, yet the difference between them is precisely of the same character as that between the variously formed flowers of some species of *Catasetum* and *Mormodes*. So utterly different are the male and female flowers of some of these species that they were at first placed by very competent botanists in different genera. It was only when the protean plants produced all the forms of flowers on one and the same spike, that it was seen that so far from belonging to different genera, they did not even belong to different species. It was left to Darwin to show what this paradoxical variation really means; and now, when we meet with a case of the kind, we say, "Ah! yes; only a sexual form," just as if we had known all about it from our earliest years, and very possibly, in our haste, mixing up, or, at least, not discriminating cases of a different nature. But this is not what we propose to discuss just now; we simply say that these cases, though often so designated, are not sports, at least in our acceptance of the term.

What, then, are sports? We have already characterized them as "bud-variations," but we must give some further indication of their peculiarities: First, as to the suddenness of their production. A tree or a shrub, all on a sudden and without any cause—that is, apparent to the eye—will put forth a bud, which, as it lengthens into a shoot, displays leaves of a different character to any that the plant has hitherto produced, which have no definite relation to any particular stage of growth and which are quite different from any that under ordinary circumstances the plant in question has produced or is likely to produce in future. In short, the occurrence is sudden and unforeseen. Gardeners, of course, avail themselves of these variations. They remove them, bud them, graft them, strike them from cuttings, or, in some way or another, endeavor to perpetuate the variety, and thus have originated our cut leaved Beeches, Maples and Limes. Thus, too, may have originated some of our weeping trees and some of our pyramidal shrubs, though, for the most part, these have, as I believe, originated as seedling variations.

Not only do these variations occur suddenly, but they are very local in their manifestation. One particular shoot "sports," while all the rest remain in their normal condition. It is very different in the case of seedling varieties, where the whole system of branches and leaves is more or less affected.

Another and a most remarkable feature about these sports is, that they sometimes occur simultaneously in widely different localities; thus the same sport of a *Chrysanthemum* "turns up" about the same time, not only in different nurseries in this country, but also on the Continent. This may be because all the plants in question have originated from one and the same stock.

These, then, are the special characteristics of a true sport. Illustrations could be given by the hundred; but neither time nor space permit, nor, indeed, for our present purpose, is it requisite to do so. Whoever will investigate the cause of these sudden outbursts of local variation must, of course, sedulously examine each case for himself according to the measure of his ability and of his opportunity. The circumstances, the history, the progress, the anatomy of each particular sport must be investigated, both absolutely and in relation to similar outgrowths in other plants. Until this is done—and it has not been done yet—any explanation as to the cause of the phenomenon must be a matter of speculation. Still, we can not help guessing, and though we may be wrong in our surmises, at least the process does good by setting us observing and thinking. Observing and thinking are processes

*The notes here published represent the substance of an unwritten address lately given to a society of gardeners. It is necessary to mention this circumstance to account for the form in which they are couched, and for the circumstance that no reference to authorities is made. This was not necessary at the time, as numerous illustrations of the things themselves were on the table. Those who desire to look into the literature of the subject should consult the writings of Meehan, Morren, Naudin and others, and will find an excellent summary in Carrière's "Production et Fixation des Variétés," and in Darwin's "Variation of Animals and Plants."

valuable to all of us, but in a particular degree to those who practice the cultural arts. And so it happens—or, at least, we will hope so—that although the causes which have been assigned for these changes are various, some, perhaps, utterly wrong, others partially so, and all more or less inadequate to explain the whole of the phenomena, yet some advantage may accrue from the discussion. An indirect benefit is better than none at all, and anything which enforces us to take some measure of the extent of our own ignorance is likely to be beneficial. We should never be a bit the better if we simply acknowledged our ignorance, as, indeed, we needs must do in any case, but directly we attempt to find out in what particulars and in what degree we are ignorant, then there is some hope that some portion of our “nescience” may be dispelled. Under this impression we may allude to one or two of the assigned causes of sporting. External causes are those which the gardener most generally invokes. For him a sport is usually the consequence of some alteration in the nutrition of the plant. It gets too much or too little food, or the food is not of a suitable character—containing too much of one thing, too little of another, or the climate is charged with the results observed. It is very convenient to have the weather to blame; it may be too hot or too cold, too moist or too dry, too brilliant or too obscure; or the soil may be at fault, the drainage may be defective, the earth not sufficiently aerated, its temperature too high or too low. Combined action of some of these conditions is, of course, possible, intermittent action equally so, whilst we, in this country, are abundantly familiar, first, with one thing in the way of the weather, and immediately afterward with another. It is, therefore, not surprising if some gardeners, without troubling themselves much to see how the explanation fits the facts, do attribute “sports” to such causes as we have mentioned. To our thinking the objections to this kind of explanation are fatal. External circumstances are, no doubt, potent enough to effect very great changes indeed. We are daily witnesses of them; but they do not produce the kind of change which we know as “sports.” On the contrary, sports occur sometimes when no alteration of external conditions is perceptible, and they do not occur when such alterations are very apparent. Or, again, they appear in one place under one set of circumstances, and at another place, simultaneously, under a different state of affairs; and although all the plants growing together have been exposed to the changed conditions of life, the sporting tendency shows itself in one particular plant only, and in one particular part of that plant, generally only in one bud. With all respect, then, for those who hold these views—and one at least of our most experienced and eminent plant-growers has lately publicly advocated them—we venture to think external causes, however adequate they may be in some cases, are inoperative in such cases as we are considering.

A better explanation is that offered by Darwin, by Naudin and others, according to which sports are due to a dissociation of mixed elements, a reversion to the character possessed by one or other of the ancestors of the plant, perhaps one or two, perhaps an indefinite number of generations ago. Let us recall for a moment what a very composite thing a plant is, even such a one as we call a simple plant. At first it is neutral and homogeneous, a mass of protoplasm—containing cells—at least so it was once said, but the homogeneity of protoplasm is a thing of the past. We don't believe in it now. On the contrary, we believe in frameworks and interstitial fluid, in granules and fibres, in some parts that are alive, others that are dead; some that are stable and immutable, others that are mobile and changeable; in short, we have come to the conclusion that, physically and mechanically, as it was previously known to be chemically, protoplasm is very much “mixed.”

Again, another of our old beliefs has been dissipated. Once we were taught that the cells of plants were closed bags without apertures, and that, while the fluid passed from cell to cell by osmosis, there were no visible pores, and no means of transmitting anything more solid than cell-sap. The passage of protoplasm from cell to cell was not then thought of as possible. But Mr. Walter Gardiner has changed all that. He, and others who have followed in his steps, have taught us how to see the pores in the cell-walls, how to see the passage of protoplasm through those pores from cell to cell, and how complacently to employ the phrase “continuity of protoplasm” in a manner that gives us, at present at least, great satisfaction. These modern discoveries of the composite nature of protoplasm, and of its passage, at certain times and under certain conditions, from cell to cell, seem to us to furnish a clue to the explanation of some of these cases of sporting as they do also in the case of some of those

curious cases in which the stock seems to influence the scion, or the scion the stock, in cases of grafting.

Again, in the life history of a plant there are several stages. There is the neutral stage, when it is, at any rate, so far as sex is concerned, an epicene. Then there is the sperm stage, when our plant consists of a mass of neutral matter, a particular portion of which is developed into sperm-cells, or into what will ultimately produce them. At another time the neutral cells of one portion of the general plant-mass develop into germ or female cells, or it may happen that both sperm and germ-cells may be developed at one and the same time, when the plant has, of course, a three-fold constitution.

All these modifications occur in the course of the life of each individual plant. But each individual plant is, necessarily, compounded of elements derived from its two parents, so that, for illustration sake, if we may consider the original stock to consist of three portions—neutral, male and female, respectively—it is obvious that in the first generation there would be six component elements; in the second, twelve; in the third, twenty-four, and so on. Who can count the generations of plants? It is enough for our purpose if we succeed in showing clearly the composite nature of plants.

This being granted, it will not seem remarkable that occasionally a partial separation takes place, just as a scum may rise to the surface of some mixed fluid, or a sediment fall to the bottom of another. This illustration may, perhaps, serve to suggest the reason for the separation of mixed elements in plants; but that is too speculative a matter for us to enter upon here. It will be better for our present purpose to note one or two examples of dissociation of mixed characters wherein both the fact and its explanation are clear. One of the most interesting is that narrated by Mr. Noble, the originator of the white form of Jackman's Clematis. Noble's Clematis, as we may here shortly call it, is the result of a cross between Jackman's Clematis and *C. patens*. Soon after this Clematis was sent out, some dissatisfaction arose because instead of producing flowers of good form and purity of coloring, more or less misshapen blooms of an unattractive appearance were formed. The matter was mysterious. The raiser was blamed by those who did not know that he is a highly competent man in his business, and one whose integrity is beyond question.

The plant was condemned. Fortunately, however, the edict was not carried out in its entirety—some specimens were left. These were watched, and in due time afforded the explanation of the mystery. Jackman's Clematis flowers in the autumn on shoots formed during the spring and summer—on the new wood, as gardeners say, just as happens with a Rose. *Clematis patens* flowers in spring on shoots that were formed during the previous summer, on the old wood, in gardening phrase. Now, when Noble's Clematis came to be scrutinized, it was found that it produced two kinds of flowers—those which expand in spring are solitary, semi-double, never white, but bluish gray, like those of *C. patens*. Those which unfold in autumn are produced in pairs and are single, like those of *C. Jackmanni*, but white. In the spring no flowers of the Jackmanni type are ever seen, and when the old wood is cut away, and only new wood thus suffered to produce flowers, no blooms of the Patens character are seen, but only those of the Jackman type.

Another very interesting case of unmixing, or, if it be preferred, of partial mixture, is afforded by Neubert's Berberis. This is a hybrid between the evergreen pinnate-leaved Mahonia and the deciduous, simple-leaved *Berberis vulgaris*, and it bears leaves some of which are intermediate in appearance, while others are like those of one or of the other of its parents.

The two illustrations above given are instances of the results of cross-fertilization, in which the whole process has, so to speak, taken place under our own eyes. But for how many centuries has the Chrysanthemum, we will say, been crossed and recrossed and crossed again? This process of crossing seems destined to come to an end because the flowers, after a time, become sterile, owing to the fact that the stamens and pistils, one or both, are imperfectly or not at all developed. Seedling variations in such cases must become more and more rare as the process of sterilization becomes more and more marked. If new seedlings are desired, raisers will have to go back to less highly modified flowers, to flowers, that is, which are more nearly in their original condition. But although the production of varieties in the Chrysanthemum by fertilization is thus limited, the development of sports by bud-variation may, and probably will, still go on, to the delight of the grower and the interest of the student. It must, however, be said that at least in the case of the Chrysanthemum the change is sometimes very slight, depending solely on the

presence of coloring matter in some cases and on its absence in others. The form of the flower and of the foliage in many of these *Chrysanthemum*-sports is in no wise different from that of the parent plant. This is only an illustration of the fact that all degrees of combination or of dissociation, as the case may be, may be expected to occur.

Is there any commingling of the elements of stock and of scion in the case of grafts? Botanists and gardeners, almost without exception, have asserted that there is none. Place on a sheet of wet blotting paper, which may represent the stock, a drier piece of the same substance, which may represent the graft, and there will be a passage of the fluid from the lower to the upper paper, but there will be no mixture of the constituents of the two.

We have always wondered if there were no reciprocal influence of stock on scion, why grafting is practiced at all, because we cannot understand the acknowledged advantages of the practice except upon the supposition of some modification being exerted. Gardeners triumphantly, as they were quite justified in doing, pointed to the millions upon millions of cases where no such modifications are visible. Botanists pointed to the closed cells from whose cavities only the thinnest of liquids could exude and permeate through the walls of adjoining cells. This was before the days of "continuity of protoplasm," as above mentioned. Now that we know that not only water, but protoplasm itself, may, under certain circumstances, pass from cell to cell, the difficulties in the way of conceiving that any influence could be exerted on the scion by the stock, or vice versa, are very materially lessened, if not entirely removed.

But before the time we speak of, there were some alleged facts which, provided the history given were true, could only be explained on the supposition of the commingling of elements by grafting and subsequent separation. In other words, the possibility of graft-hybridization must be assumed. Whether it has been proved is another matter.

One of the strongest cases in its favor that we know of is that of the famous Adams' *Laburnum Cytisus Adami*. We cannot go into detail as to the history of this extraordinary tree. It must suffice to say, that it is stated to have originated from the implantation of a bud of the dwarf, shrubby, lilac-flowered *Cytisus purpureus* onto the common *Laburnum*. Be this as it may, we have in our gardens on this side of the Atlantic trees which every year astonish the beholder by producing, together with the foliage and flowers of the *Laburnum*, tufts of *Cytisus purpureus* and all sorts of intermediate conditions between the two. If the stock exerted no influence on the scion, the buds should be pure *Cytisus purpureus* and pure *C. Laburnum*, without any intermediate forms. It would lead me too far to give other illustrations of the production of shoots of an intermediate character between stock and scion. Many such are on record, and many have come under my own notice. It must suffice for me to show that whilst we may, with a very great amount of probability, attribute the existence of some sports to the "un-mixing" of elements blended by means of cross-fertilization, whether between species (hybrids), or between varieties (cross-breds). We may, likewise, but with a less degree of probability, attribute the existence of others to a similar dissociation in the case of grafted plants.

Obviously the latter cases must be much less numerous than the former, and are purely artificial productions, not likely to occur in Nature.

Other assigned causes appear to me to pertain rather to variation in general than to that limited, localized form of it which is here considered as bud-variation, and may be here passed with the mere mention.

New or Little Known Plants.

Syringa Pekinensis.

THIS plant (Fig. 30) flowered in the Arnold Arboretum and in one or two other gardens near Boston last June for the first time, having been raised from seed sent from Pekin by Dr. Bretschneider.

Syringa Pekinensis is a wide-spreading shrub with slender branches covered with light yellow-brown bark, marked with minute wart-like excrescences, and rather stout winter-buds, with broadly ovate, blunt, membranaceous, chestnut-brown scales, with scarious, ciliolate margins. The terminal bud, as is the case always with the common Lilac, does not develop. The bark of the principal stems is thin and light yel-

low, separating into delicate flakes, and is not unlike that of a young Yellow Birch-tree. The leaves are ovate or deltoid, obtuse or acuminate, rounded at the base or gradually contracted into a slender-channeled petiole. They are dark green, opaque on the upper, and rather paler on the lower surface. The inflorescence is a short, compact thyrsus, only four to six inches long, surrounded and much covered by the shoots of the year, which complete their growth before the flowers open. These are white, with a membranaceous, nearly entire calyx enclosing the short tube of the corolla, and emit a disagreeable odor not unlike that of the flowers of the common Privet, which they much resemble.

Mr. Hemsley refers *Syringa Pekinensis*, in his enumeration of Chinese plants, to *S. Amurensis*, and judged by the plants in cultivation in the Arboretum, he is doubtless correct in doing so, although, from a garden point of view, the habits of the two plants are so dissimilar that it may be well, perhaps, for cultural purposes, to retain the two names. The flowers of these two plants are indistinguishable, and the leaves vary only in size. The color of the bark of the branches is the same in both, and so are the scales of the winter-buds. *Syringa Pekinensis* has, however, much more slender branches than the Amoor plant; the winter-buds are smaller, and its whole habit and appearance are lighter and more graceful. The inflorescence is smaller, more compact and less showy. *Syringa Pekinensis* is evidently not free-blooming, in its young state at least. The plants were ten feet high in the Arboretum before they flowered at all, and when a few of them did flower at last, these large plants bore three or four small panicles only.

Syringa Pekinensis, judged by the little that is now known of it in gardens, is the least valuable of all the Liliacs as a flowering plant. It is very hardy, however, and grows rapidly, and its habit is good. The plants all show a tendency to develop pendulous branches, and it was one of the Arboretum seedlings, in which this tendency was rather more strongly developed than usual, which was the origin of the so-called "Weeping Lilac," which has been unduly extolled, in view of the fact that nothing was known at all until last year about the flowers. Now that the plant has flowered, it is seen how very far it falls short of what has been claimed for it.

Foreign Correspondence.

London Letter.

ROYAL HORTICULTURAL SOCIETY.—An exhibition of more than ordinary interest was the result of the meeting held on Tuesday last at Westminster. Orchids were represented by large groups of Dendrobiums, among which the following were conspicuous: *D. Aspasia* ×, raised by Messrs. Veitch from *D. aureum* and *D. Wardianum*. It has the pseudo-bulbs and habit of the last named, and large, prettily marked, fragrant flowers, in which the colors and form of both parents are blended; *D. lituiflorum superbum* (Sander & Co.), remarkable for the large size and deep color of its flowers; *D. signatum* and *D. Smillie*. Well flowered plants of *Phajus tuberculatus* and a beautiful example of the new hybrid raised by Mr. Cookson from the last named and *P. Wallichii*, were among Mr. Sander's exhibits, as also was a plant in flower of the rare and elegant little *Cypripedium Schomburgkianum*, which has been lately introduced from the regions of the Roraima in British Guiana. A charming variety of *Odontoglossum Pescatorei*, named *melanocentrum*, bearing a stout, branched spike of flowers, which are large and pure white, with a blotch of purplish crimson on the base of the lip, came from Mr. Tantz, of Hammersmith. *Lycaste Skinneri*, Young's variety, is distinct and decidedly pretty in the tinting of its flowers, which are of medium size, pure white, the lip and petals tinged with a pale coppery hue. Several hybrid *Cypripediums*, interesting only as hybrids, but of no beauty, were exhibited, and a plant of the singular hybrid *Cymbidium*, raised by Messrs. Veitch from *C. eburneum* and *C. Lowianum*, was also shown in flower. A collection of plants sent from Kew comprised *Godwinia gigas* in flower, the spathe deep purple, boat-shaped, twenty-one inches long and six inches wide; *Dracontium*

Carderi, like the *Godwinia*, but smaller; *Arisæma speciosum*, large examples; and *A. præcox*; a large specimen of *Tacca ariocarpifolia*, with flowers on stalks eight feet high, and the subject of much interest and speculation, most people being unacquainted with it; *Strelitzia Nicolai*, the flower-spike bearing its large, strangely formed, white and blue flowers; *Buphane toxicaria*, the poison-bulb of the Kaffirs, bearing a head of flowers a foot across, and suggesting some of the *Hæmanthi*; *Echmea glomerata*, whose large, stout spike of blue flowers, springing from compact, cushion-like clusters of scarlet bracts, is both handsome and singular; *Brownea Ariza*, a fine head of rosy red flowers; *Rondeletia amæna*, a handsome stove shrub, with large, oblong leaves and compact terminal bunches of pale flesh-colored flowers.

A double-stemmed plant of the new and delightful little

now a most successful breeder and grower of these plants, many of his seedlings being almost, if not quite, equal to the best hitherto raised. The majority, however, of the very best among garden *Hippeastrums* we owe to the skill of Messrs. Veitch, of Chelsea, who have raised an enormous number of kinds since they commenced operations with these plants, twenty-three years ago. In a paper read by Mr. H. Veitch on Tuesday last, at the meeting of the Royal Horticultural Society, the subject of *Hippeastrums* and their culture was treated in a most interesting and instructive manner. An exhibit of plants in flower, representing the species, first hybrids and the choicest of the seedlings raised from them, formed a perfect object-lesson, and showed much better than any words could how great an improvement had been made in the flowers by breeding. As an illustration of what can be done by

Fig. 30.—*Syringa Pekinensis*.—See page 164.

Phœnix Rabelini was exhibited, and received, as it deserved, a first-class certificate.

HYBRID HIPPEASTRUMS.—The magnificent garden race of *Hippeastrums* which we now possess is the result of nearly a century's careful breeding and selecting from such of the species as possessed the qualities necessary in a good breeder. According to Herbert, the first hybrid *Amaryllid* that appeared in our gardens was the mule between *H. vittatum* and *H. regium*, which was raised by a nurseryman named Johnson in 1810 and named *Johnsoni*. In the following year Herbert himself raised several hybrids, and in his "*Amaryllidaceæ*," published in 1837, he enumerates thirty-one hybrid *Hippeastrums* which had been raised in England. His observations on this genus and his success in breeding from the species were no doubt the cause of the work being taken up by the late M. Louis Van Houtte, of Ghent, and by the elder De Graaf, both of whom raised many hybrids and crosses. De Graaf the younger is

means of hybridizing and selecting to alter and improve the character of flowers so as to bring them up to the florist's standard of excellence, the exhibit and paper by Mr. Veitch were simply perfection. From the form, substance and color of the progenitors, such as *H. Leopoldii* and *H. equistris*, to those of some of the latest of Messrs. Veitch's seedlings, such as that called *Champion*, is a really marvelous advance to have achieved. *Champion* has a shallow tube of great substance, the segments each four inches wide, the whole flower measuring eleven inches in diameter. Its color is rich crimson-scarlet, with a velvety sheen and a small star of green at the base of the tube.

The species first employed as breeders by Messrs. Veitch were *H. pardinum* and *H. Leopoldii*, both introduced by themselves from Peru. The result of this cross did not prove satisfactory, neither did a cross between the last named and *H. aulicum*. When a mule was crossed again with one of its parents, the offspring were, as a rule, almost identical with the

species, the characters of the mule being scarcely shown. The most important "break" was obtained by crossing *H. Leopoldii* with a seedling named Empress of India, these two yielding a race which Messrs. Veitch at once saw was capable of being moulded into one of considerable garden value. A large number of the most popular kinds have resulted from this cross. A serious defect in the earlier hybrids, which runs through almost all the species of *Hippeastrum*, is the large star-like blotch of green at the base of the tube, giving the flowers a coarse and sometimes ugly appearance. To get rid of this defect has been the aim of Messrs. Veitch for some years, and that they have succeeded was abundantly evident in the varieties exhibited.

A race of kinds which flower in the autumn was the outcome of breeding from *H. Leopoldii* and *H. reticulatum*, the latter a free-flowering plant of elegant habit, with a broad band of white along the mid-rib of the leaf. It blooms in September and is evergreen. In the progeny of these we have such handsome seedlings as Mrs. Garfield, Mrs. Lee and Autumn Beauty.

Of the thirty-eight species of *Hippeastrum* recognized by Mr. Baker in his recently published monograph, only very few are now in cultivation in England. Invariably, when a race of any genus has been obtained in gardens and is superior in horticultural characters to the species themselves, the latter are allowed to drop out of cultivation. Efforts have been made at Kew to procure all the species possible, but so far there are only thirteen species represented.

The cultural directions given in Mr. Veitch's paper are of special value—nowhere are these plants grown so well as at the Chelsea Nursery, where a large house is devoted to their culture, and where the plants, when in flower, form a magnificent picture. Whatever may be the case in America, here in England the *Hippeastrums* are often a failure in ordinary gardens. The chief cause of failure is, no doubt, the same as in the case of many bulbous plants—namely, neglect to allow the plants sufficient rest by withholding water and exposing them to sun and air. Excessive watering is, as Mr. Veitch stated, most fatal to these plants. They like plenty when in active growth, but it must be entirely withheld during the season of ripening and rest.

The soil recommended by Mr. Veitch is two parts loam, one part rotten cow-manure and one part sand, the whole to be mixed and exposed to the air for about three months before it is used. Pots should always be small in comparison with the size of the bulb, and they should be well drained. The plants are repotted annually by Messrs. Veitch, though some growers prefer to repot only every two years. All the soil is shaken off the roots, the dead ones cut away and any rotten scales removed from the bulbs. This is done in January, when the plants are repotted. They are placed in a temperature of fifty-five degrees Fahr. for a fortnight and then plunged in a bed of tan, the temperature being raised five degrees higher. Air is given on all bright, warm days, but the plants are never shaded. The flowers develop within about ten weeks after the plants have been repotted. When they have ceased growing the plants are taken out of the tan, less water is given, and the house is kept drier and more airy.

Cultural Department.

The Potato.

THE first great advance in perfecting the quality of the Potato was made in the production of the Mercer variety, which was named after the county in New York where it originated. Being large, white-fleshed and mealy, it soon took the preference over the Blueskin, Foxsite and other varieties of the period, and spread throughout the country from Maine to the far west. In time the Mercer deteriorated, became subject to disease, and the plants decayed prematurely.

The potato-rot of 1844 and in later years worked a revolution in Potato culture, mainly through the wisdom of the Rev. Chauncey E. Goodrich, chaplain of the Insane Hospital at Utica, who conceived the idea that to make the tubers hardy they should be reproduced from wild Peruvian and Chilian stock. With this view he imported wild tubers in the years 1849, 1850 and 1851, and by cultivation produced in 1853 the Garnet Chili, which became the parent of a long line of hardy, improved, palatable, white-fleshed tubers obtained by hybridization. Mr. Goodrich is credited in Europe with having established a new era in Potato growing, from the thousands of seedlings which he tried and distributed for trial. His work was one of pure philanthropy. Other men made large

sums of money out of his valuable novelties, while he contented himself with the good he was doing to humanity. He died poor, when perhaps he ought to have been more provident, as his daughters were obliged to live by teaching.

Wild Chilian Potatoes have also quite recently been tested and found unusually hardy by my correspondent, the celebrated botanist and seedsman, M. Henrie Vilmoren, of Paris, who is celebrated for his zeal in introducing and domesticating wild esculents. Although Baron von Humboldt stated that there were no Potatoes under cultivation in Mexico at the time of the conquest, wild tubers from her mountain lands have been grown in France and in this vicinity. The effect of cultivating wild tubers in a rich soil is shown by a persevering experiment made by Mr. Alfred Rose, of Yates County, New York. About the year 1879 he planted one wild potato of the size of a pea and obtained as a product one tuber of the same size. Such a result would have ended the trial with many; but he planted this little product and obtained a tuber of the size of a large pear, which, being planted, did still better, until in the sixth season there was a product of nine tubers, the planting of which, in the seventh summer, yielded nearly two bushels of smooth, handsome potatoes, weighing from four ounces to a pound each.

The experiments of Goodrich deserve repeating on a much larger scale, and with wild tubers of California, Arizona, Texas, Mexico, Central America, Peru and Chili. Selections of these should be used in hybridization, and their seed-products planted and tested until new, valuable and hardy potatoes are obtained for the table. There was a fortune in the production of Bresee's Early Rose, and this result may be repeated. Our late Secretary, Mr. A. W. Harrison, gave this potato its name from its character and color, and on one occasion he made an exhibition of some of Mr. Goodrich's seedlings in bushels at the autumnal fair of our society, raised by him in Germantown.

Fabulous sums were paid for the Early Rose the year of its production. I have known of \$20 having been paid for a peck, \$3 for a pound and \$2 for a five-ounce tuber, this last by the late Peter Henderson, who produced from it a crop of 450 pounds from 150 plants raised by forcing, sprouting and rooting. By this system, in a hot-bed, 2,000 plants, and almost 2,000 pounds of potatoes, have been produced from one pound, or by measure thirty-three bushels, of Ruby Potatoes, worth at the time \$74.

The value of a new Potato does not depend altogether upon its size, form, productiveness, hardness and taste; for we must also consider the proportion of starch which it yields by analysis, a test of quality which is too seldom employed. On the average a potato will yield in October from eighteen to twenty per cent. of starch and seventy-five per cent. of water, but the former ranges from ten to twenty-three per cent., and the latter from sixty-eight to eighty-two per cent. The starch exists in the largest proportion in October, and diminishes gradually until April, when the loss is sometimes as much as three per cent.

Potatoes should be boiled in their skins if economy is to be considered, as the loss to the water is then only three per cent. as against fourteen where they have been pared; or from two to three ounces in the pound, which is a very considerable waste.

As the Potato plant and tuber contain a large proportion of potash, this alkali is an important element in the plant-food for a crop of tubers. Mr. Harrison grew his valuable crop of Goodrich seedlings on a piece of what was rated as worn-out land, by the aid of an abundant dressing of wood-ashes.

The potatoes of to-day are quite different in appearance from those grown fifty years ago, when their eyes were much sunken, and their surfaces covered with nodules. American tubers are much more symmetrically formed than those of foreign countries in general, and of more uniform size. Very large tubers evince a richness of soil, but are no special advantage to the consumer. Russia produces very large potatoes, but they have deeply set eyes, and are not invitingly-shaped. The tubers of Europe are generally light yellow in flesh; some are very dark-skinned; and the more common shape is short and thick. Selection of shapes for planting should improve the form of the potato, as it has done with the tomato. "Plant the best, and eat or sell the balance," is a rule that holds good for crops in general; but it is a difficult one to secure acquiescence in among the ignorant and improvident. Following just the opposite in Ireland has had much to do with her potato failures and famines. It is a self-denial not to eat the best of the crop, when the lower grades will sprout and grow, but this self-denial pays in the end, whether it be in the potato, Indian corn or wheat.—From a paper read before the Pennsylvania Horticultural Society by Robert P. Harris, M.D.

Fig. 31.—A Sugar Maple in New Hampshire.—See page 166.

Some Hardy Trees and Shrubs.

I HAVE just read the notes of Mr. Jack, under the heading of "Exotic Shrubs in Canada," and wish to say that the shrubs found hardy near Montreal are equally hardy in our dry interior climate. The Yellow-wood (*Cladrastis lutea*) we are surprised to find a true iron-clad during our recent trying seasons. This is remarkable, as we have found no other tree or shrub from the south truly hardy here, and even the forest-trees and shrubs of the New England States fail to endure our hot, dry summers and cold winters. *Rosa rugosa* is perfect here, but this is not strange, as I believe it to be indigenous to extreme east Europe and north-central Asia. We have varieties of it from east-central Russia that do not differ materially from those we have from China and Japan, and we have nearly double varieties which we were told originated long ago in west Asia. One of these has quite large, dark purple, fragrant flowers, with an average of over forty petals. All the Caraganas are perfect here, and *C. arborescens* is decidedly tree-like in habit. Some of the large-flowering dwarf species, top-worked on *C. arborescens*, make very desirable miniature trees for lawns. We have some specimens that attract more attention than any trees on the grounds.

The many varieties of the Bush Honeysuckles from east Europe and north-central Asia are perfect here, and the same is true of all the species and varieties of Philadelphus except those from south Europe and south Asia.

Of the Forsythias we find *F. suspensa* the hardiest, and, if properly trained on a trellis, by far the most ornamental. *Euonymus nanus* is a native of the north slopes of the Caucasus range and of the steppes north of it, and it proves perfectly at home on our prairies. Aside from the conifers, it is the only plant that holds its leaves with perfect color during the whole winter. It fruits with us very abundantly, which, I believe, it does not do in south Europe, and I suspect not very perfectly at Boston or Montreal.

Hydrangea paniculata is perfect in plant and flower with us, and I suspect its original home was north-central Asia.

Tamarix tetrandra we have not tried; but *T. Amurensis* is hardy with us, and a far better plant than *T. Germanica*, which is tender.

Ames, Iowa.

J. L. Budd.

Chrysanthemums in Pots.—I.

AS between planting out Chrysanthemums and growing them continuously in pots, opinions vary. Those who plant, argue that less attention is required and larger plants are obtained. My experience is, that for all purposes continuously pot-grown plants are preferable, and especially is this true of those required for specimen plants; while with pot-grown plants for specimen blooms more substance and better color are obtained.

The methods of growers vary. Some use elaborate compositions of soil, mixed with almost chemical exactness; others are satisfied with any ordinary rich loam, believing, as I do, that it is the after-treatment that counts. Some give as many as three changes, or shifts, before the final potting, which they make in June; others only two, and make the final shift in May. Some rigorously remove all suckers as they appear; others vary their practice with different varieties.

The soil used from the first shift onward should be composed of some good, light, fibrous loam, being turf laid up the fall previously, alternately layered with cow-manure and road-scrappings. If heavy loam only be available, horse-manure had better be substituted. A little lime might be beneficial, but is not essential. What is important, is to have good loam in a moderately dry state and to pack it firmly, leaving the feeding of the plants until later in the season.

Presuming plants are well established in three or four-inch pots by the first week in April, I would shift at once into six-inch pots if intended ultimately for tens, and into seven-inch pots if intended for twelves. The plants should have been stopped once, but if this has not been done, the work should be delayed for a week, until they are somewhat established. Unless there be good light and facilities for airing in the greenhouse, the plants should be moved into a cold frame by the second week in April, plunged in sand and protected at night until all danger of frost is past. The final potting may then begin and it may extend over two weeks, beginning with the earlier and stronger varieties intended for ten-inch pots, giving the weaker-growing varieties and those intended for the largest pots a little more time. I take particular pains to have the pots clean, inside as well as out, and well drained. The soil is packed quite firmly, leaving about two inches for watering or a top dressing, if it should seem necessary. Water

should be given sparingly for a week or ten days, unless the weather be very dry. I would rather return them to the frames so as to be able to lay over a few sashes during heavy rains. This is more important than it may seem, as a heavy soaking before new roots have developed is really injurious.

We plunge the pots in the ground nearly to the rims, three feet apart and four between the rows. Last year a potter made for us circular disks of earthenware, six inches in diameter by one thick, with a bore in the centre two inches wide; these are set into the ground and the pots are placed upon them. This contrivance, simple as it is, keeps the drainage free, as it effectually prevents worms from entering the pots from the ground. The clogging of the drainage in pots by worms has always been a great obstacle to growing plants in pots, especially during the feeding season, when free passage of water is essential.

I hose my plants freely after bright days during June and July—a practice which keeps the plants clean, and which seems beneficial in other ways which I cannot explain.

Wellesley, Mass.

T. D. Hatfield.

Easter Plants.

THE use of flowering plants in special decorations for Easter observances is increasing, and not only in decorations, for it seems in many instances that a Lily or some other plant in flower is preferred to the elaborate Easter card of previous seasons.

The increase of these pleasant customs is, of course, a profitable thing for the florist, though with the extended demand there has also been a great increase in the supply; in fact, the supply may be too abundant, and in consequence lower prices may prevail. But while this class of business counts as an important item in many commercial establishments, it requires much care on the part of the grower. For instance, one may be preparing a large lot of *Lilium longiflorum*, and if so it will be found practically impossible to induce all the plants in a thousand or more bulbs to grow at the same rate, even though under apparently the same conditions, and in consequence the more forward plants must be sorted out and placed in a cooler temperature so as to allow the remainder of the lot to catch up with them; or the slow growers must be hurried by increased heat and feeding. In fact, this sorting operation may have to be gone through several times, so as to bring the entire lot into an even condition by the week before Easter.

There still exists a considerable difference of opinion as to the respective claims of *Lilium Harrisii* and *Lilium longiflorum* for Easter work. Of course it is admitted that for early forcing *L. Harrisii* is superior, and in size of flower it also takes the lead, but for actual beauty and for lasting qualities *L. longiflorum* still holds its own, and its flowers not being pendant the plants can be packed much more readily for transportation.

The Ascension Lily, as it is sometimes called (*Lilium candidum*), is also grown in quantity in some localities for Easter use, and while not so showy as the preceding sorts, is very beautiful, and especially useful for cutting.

Lilium candidum will not bear hard forcing, and consequently should be started into growth so early that it may be kept in a cool house, because when exposed to too high a temperature the loss of the lower leaves usually follows, and thus the full beauty of the plant is lost.

Next in importance to the Liliums among Easter plants may be mentioned the Hydrangeas, the forcing of which has attained large proportions of late years, though the prevalence of cloudy, dark weather during the present season, together with an early Easter, has somewhat upset the calculations of producers. Still, among so large a number of growers near the various floral centres, it is scarcely likely that there will be a Hydrangea famine this year.

As to varieties for forcing, *H. hortensis* and *H. Thomas Hogg* take the lead and in the order named, though the latter is purer in color than the former, and where white is essential, of course it takes first place. *Azalea Indica* in variety is indispensable at this season, large quantities being annually imported from Belgium for this purpose, in addition to the multitude of home-grown plants used in the same way.

The plants imported last fall have not, however, been entirely satisfactory, many of them having been nipped by frost before shipment, and thereby lost their buds.

For early work the favorite varieties are among the following: Deutsche Perle, double white; Fielder's White; Madame Van der Cruyssen, deep rose, and one of the best of its color; Eugene Mazel, red with dark blotch; and for cut-flower work *Indica alba* must not be omitted.

The bright yellow flowers of *Cytisus racemosus* (or *fragens*) are also much appreciated; in fact, this may be said to be the most useful yellow-flowered plant for decorative purposes during the winter and spring months, its long racemes of flowers hanging down or standing out in accordance with the arrangement in view, but always graceful and pleasantly fragrant.

This *Cytisus* is readily rooted during the spring, and if potted on as the roots require more space and pinched back occasionally, will make shapely plants of fair size for use the following season. Lily-of-the-Valley, in flats and in pots, finds a ready sale, as do Daffodils and Tulips, the varieties of the latter that are used in this way being few in number, and comprising about half-a-dozen sorts of those generally used for forcing.

Freesia refracta alba is also to be had in pots, but does not seem to become as popular as Hyacinths. In fact, the market soon becomes overloaded with it, even in the winter. Marguerites and Pot Roses, the latter being mostly of the H. P. and China classes, are also plentiful and in good demand.

The Spring Garden.

SCILLA ANTI-TAURICA.—Among a number of early flowering Asia Minor bulbs with which Mr. Edward Whittall, the well known collector, favored me last fall, the above, now in flower, proves a gem, being not only very early, but probably the brightest *Scilla* yet introduced. The color is quite as bright as that of *Chionodoxa Sardensis*, and the flowers are as large. The nodding flowers are borne on rather short scapes, but this may be because the bulbs are not well established. This, however, is scarcely a fault, since the flowers cluster prettily among the leaves. A *Scilla* as bright as the *Chionodoxa* and with the superior foliage of the genus is a distinct gain, and lovers of fine hardy plants should note this variety.

Another Anti-Taurian *Scilla* bloomed in February; a very dwarf variety with three leaves and a single scape with a single nodding flower of the color of *S. Sibirica*. This might well be named *S. uniflora* were the name not already a synonym of *S. Sibirica*. The bulbs of this variety are singular in having a thin, reddish skin, like the Hyacinth. A third plant proves to be the early flowered blue Muscari, alluded to in a former article. The *Scilla bifolia* collected by Mr. Whittall proves to be identical with the European *S. bifolia*, having the same slaty blue, upright flowers borne on waving scapes. Blue, white and rose varieties of *S. bifolia* are all choice plants for the early garden. *Scilla trifolia* is another find of Mr. Whittall's, but being in a rather cold spot it has not yet bloomed with me. It perhaps may not be known to some readers of GARDEN AND FOREST that Mr. Whittall is an amateur, long resident in the East, who discovered in his hunting expeditions the richness of the flora of Asia Minor, especially in bulbous plants, many of which were either rare or quite unknown to cultivation. He has taken up the task of having a systematic collection of the flora made for his garden, and incidentally collects a surplus. We are already indebted to him for supplies of *Chionodoxas* in several varieties, Snowdrops, *Scillas* and *Anemone blanda*. Several new Frittellarias have been distributed this season, on which I hope to report soon.

Double Cropping in the Garden.

IT is not practicable in all gardens to grow more than one crop in a season. Land free from stone and clay, lying high, dry and level, is best suited for such attempts. A good way to begin is to plow in a heavy coat of manure in fall, and in winter or early spring to spread on as much more. This, worked into the soil as soon as it is dry in spring, with plow and harrow, furnishes food enough to carry two crops with the help of special fertilizers applied during the growing season.

Cabbage and Lettuce can grow together in rows three feet apart, the plants of Cabbage two and a half feet apart in the rows, with Lettuce between. Setting a row of Lettuce between each row would double the crop, but would necessitate hoeing by hand. Early Onion sets can be followed by Cucumbers. Onion seed sown in groups of six rows, with the next space left for a row of Celery, is a good arrangement, as the Onions can be off before it is time to bank the Celery. Spinach and Peas (of the dwarf varieties) make a good first crop, to be succeeded by Celery; early Beets and Sweet Corn hold the ground almost too long for the advantage of the Celery crop; Horse-radish set between plants of early Cabbage will come

to maturity after the Cabbage is removed, and make good roots in one season's growth, if a small root six inches long is dropped into a hole eight inches deep every two feet when the rows are three feet apart at least. Early Radish or Spinach, between rows of Horse-radish, leave the ground early and give a long season for the Horse-radish. Beans can follow early Peas if planted by the 1st of July. Cucumbers planted the first week in July may succeed Spinach. Late Spinach can follow early Beets, and two crops of Beets—the last one sown July 15th—are not an impossibility. Two crops of Cabbage—an early and a late—can be grown on the same land, but a good season is necessary, and prompt connection between one crop and the other.

This double-cropping pays only on well-manured land, and should not be undertaken without such preparation. The secret of success is in supplying abundant plant-food to the growing crops, in soluble form, to make a quick growth. Perhaps there is nothing better for such a special fertilizer, applied in May and July, than nitrate of soda—broadcast and hoed into the soil. Its action is rapid and soon spent, and an over-application is a waste, as the plants only appropriate a small quantity. In dry times water must be supplied to carry along the crops. One great drawback in double-cropping is the tramping down and compacting the land, in the work necessary to keep the crops free of weeds and gather one crop, while not injuring the other, especially when both crops grow till July on the same ground. The earlier the first crop is removed the better, and the clearing of one crop before the other is placed in the land gives an opportunity to turn up the soil afresh. Where the horse can be used between rows less hand work of course is necessary, but double-cropping increases very much the area of the garden, and quickly-grown vegetables are much better than others.

West Springfield, Mass.

Phajus tuberculosus.

THE representatives of the genus *Phajus* are rather more than twenty in number, and most of them are worthy of cultivation. This is particularly the case with the species now under consideration, as it is certainly one of the most beautiful in the genus. It has been known to botanical science for many years, and has passed under the generic names of *Bletia* and *Limodorum*. Until about ten years ago, however, it had not been in cultivation, and its appearance was then due to M. Léon Humblot, a young Frenchman, who succeeded in sending plants to Messrs. F. Sander & Co., St. Albans. On the homeward journey many plants died, but the few that were left commanded good prices at the London salesrooms. These have now been further augmented by a fresh importation, which Messrs. Sander received last year through the same traveler, and we may expect that this Orchid will be much oftener seen in future. Several plants from this last consignment are now flowering here in the nursery, and I have thus been able to make the following description from them: The dark green annulated stems, which are not quite so thick as one's little finger, are somewhat swollen at the base, and at the summit bear five or six lanceolate-acuminate, plaited leaves, nine to twelve inches long, and about two inches across in the widest portion. The stout, erect peduncle springs from below the leaves, and in the specimens seen has borne from six to ten large and handsome flowers, the white, twisted pedicels of which are furnished with a pale green spathaceous bract at the base. The broadly lanceolate-acute sepals and petals are pure white, less than two inches long, the former having a slightly raised median keel on the outer surface. To these a striking and attractive contrast is presented by the large three-lobed lip, the side lobes of which form a tube by meeting over the white and slender column. The inner surface of the side lobes is pale yellow, densely covered with deep brown spots, and there are also numerous silky hairs. The much-crisped middle lobe, which is cleft in front, is white, with numerous blotches of pale mauve near the edges, while on the anterior portion of the disc is a raised bright yellow, warty crest, and at the very base almost is a large tuft of erect, pale yellow, silky hairs.

This species is a native of the warm malarial swamps of the interior of Madagascar, and he who would possess it must run the risk of being stricken down at any moment by fever or other diseases, of which there seem to be many, according to travelers' accounts. Indeed, M. Humblot's constitution suffered so much by his last journey into the interior that he came home to France with the expectation of dying, but happily he has again recovered his health. A warm and moist atmosphere are the chief requisites for growing this *Phajus* successfully, the soil being a matter of little moment, as the

plants thrive just as well in peat as when grown simply in moss and fixed on a teak raft. Plenty of water must be given, but the chief danger to be guarded against is letting the soil or moss become sour or sodden by stagnant water. The winter temperature should be kept up to about seventy to eighty degrees Fahrenheit, and this, in conjunction with plenty of moisture as recommended, seems to be all that is of importance to induce the plants to produce their flowers freely. No doubt as this species gets more accustomed to the empiric art of the gardener, it may thrive at a somewhat lower temperature and under less exacting circumstances.

St. Albans, Eng.

John Weathers.

Heuchera sanguinea.—I am pleased to be able to record the hardiness of this plant during the past winter, having left one out without the slightest protection as a test plant. It may be said that the last was not fairly a test winter; but with such plants as are evergreen and have their growing parts all above ground, as in *Heuchera sanguinea*, the fluctuations of temperature are more injurious than a continued period of severe weather, for under the one the plants are often incited into premature growth, and thus more easily killed, while during protracted severe weather the usual accompaniment of a coat of snow is the best possible protection against both sun and frost.

Aubrietia Leichtlini.—This new *Aubrietia* is now flowering with us for the first time, and if proof were necessary of its value as a garden plant other than that contained in the specific name the plant bears, it will be found in the decided bright rose color of the flowers. As is well known, all other *Aubrietias* have flowers of various shades of violet-blue, and their value as spring decorative plants for association with such plants as the varieties of the Moss Pink for spring effect cannot be overestimated. *Aubrietias* supply the one tint lacking in the many varieties of *Phlox subulata*. They are easily raised from seed; but if it is desired to perpetuate any particular variety, this must be done by division and cuttings in fall, as seedling plants vary considerably, especially where more than one variety is cultivated; so, taking into consideration this fact, it is safe to advise that *A. Leichtlini* be propagated by division. We once had a white *Aubrietia* under cultivation, but soon discarded it, owing to the insignificance of its flowers, which were no better than those of the common Chickweed.

Correspondence.

Some Practices in Grafting.

To the Editor of GARDEN AND FOREST:

Sir.—The art of grafting, like nearly all other arts, has had much new light thrown upon it during the past generation, and some of its abuses have already been pointed out and corrected. There remains, however, something still to do in calling attention to some misuses of the art, which, next to that of the hybridizer, is the most fascinating of horticultural processes. It is well to discuss its scientific side, and show all that can be shown of the almost infinitely varied influences of stock on cion and cion on stock.

It is desirable also to keep in full view the practical, everyday side of the matter. Some friends of gardening in England have fallen into the belief that because many ill-assorted unions of trees are sold and bring loss and disappointment, the whole practice had better be abandoned. Not many will agree with such a sweeping condemnation, but there is good reason to look carefully into the misapplication of the art. When a whole section of a country engaged in fruit-growing finds that a certain fruit grafted on a given stock cankers and fails, we cannot blame people if they try other stocks, and finally settle down to the practice of growing this fruit on its own roots, if it does better so. When a tree is so short-lived on another stock as to be valueless in two or three years, it is folly for nurserymen to continue its propagation in that way. A choice variety of anything grafted upon a stock which is absolutely sure to send up a multitude of suckers and overwhelm it, is a delusion and a loss, and this loss falls heaviest, finally, on the nursery trade.

An instance of this is the budding or grafting of the new varieties of Lilacs upon a stock of common Lilac, as are all those sent out from European nurseries. An example of a good plant on a stock where it will live but a very few years is *Prunus triloba*, the so-called Flowering Almond on Plum or Peach stocks. A mere touch separates the plant from the stock. Another is found in the working of the Rose *Acacia* on *Robinia Pseudacacia* with precisely the same results. So long has this sort of propagation been practiced that I know of many nurserymen, both in this country and Europe, who

have never seen either the Flowering Almond or the Rose *Acacia* on its own roots, and some have even told me that neither would grow in that way. I have had the pleasure of sending specimens on their own roots to the unbelievers. There are really many things that would be far better on their own roots than grafted upon any other stock whatever, and there exists no sound reason for grafting such things at all. Some of this sort are the following: Wier's Cut-leaved Maple, most varieties of Elm and every sort of grafted shrub on stock which suckers, since they can all be layered so very easily. The Plum on Peach stock may serve a useful purpose on sandy soils, but the indiscriminate sending out of budded Plum-trees is working untold harm to the general nursery trade.

The use of a tender stock for plants which must endure a greater degree of cold than the stock can stand is illustrated by the use of *Rhododendron Ponticum* as stock for *R. Catawbiense* hybrids. It has caused considerable losses of this beautiful plant in Massachusetts, and the best growers now see the desirability of raising them all from layers on their roots.

Another plant that is far better on its own roots is the Quince. As grown now, the new sorts of Quince are budded on the common sort, which, after a few years, send up suckers on every side, and these are very difficult to distinguish. Why not grow these choice sorts from layers or cuttings? The double and also the white *Wistarias* are now almost universally grafted on the common purple sort, and they are often ruined by the more vigorous suckers of the stock. Why do we graft such a plant at all, when by getting them on their own roots by layering we can then multiply them ad infinitum, by root cuttings, as easily as we can raise Peas?

Much labor is applied to the grafting of such trees as the Purple, Cut-leaved and Weeping Beeches, which are very difficult to graft out-of-doors, when they might be far more cheaply and better multiplied by layers. I was greatly interested in a well known, huge Beech, in Kew gardens, last season, which has rooted the tips of its immense, horizontal branches into the soil, and produced, at each of these reinforced points, a large and finely formed tree, so that a ring of these now surrounds the plant. The perfect success of these layers showed what could be done by this method in multiplying these fine trees.

The evident truth is that we often take the worse and more expensive way of propagating many useful plants simply through habit.

Cambridge, Mass.

F. L. Temple.

Longevity of the Elm.

To the Editor of GARDEN AND FOREST:

Sir.—There are several of our eastern trees—the Sycamore and the Tulip-tree, for instance—which attain much greater size than the White Elm. But the finest specimens of original growth—noble individuals, whose commanding stature required the lapse of many centuries—were ruthlessly swept off in the times of early settlement; and it happens now that in most of the older parts of the country the champion trees for size are Elms.

Dr. Holmes, who, in his lively way, has "interviewed" various notable individual Elms of New England, gives it as the result of his observations, that the species is not long lived, and he doubts whether any last beyond two or three centuries. Is this limit well substantiated? Data pertaining to the age of a tree are seldom obtainable. All its early years it is in no way conspicuous among its fellows, as is so frequently the case with the adolescence of centenarian claimants; and in such cases questions of longevity are difficult to decide.

There is an Elm in this town whose trunk, in the smallest place between roots and branches, girths nineteen feet three inches; this at five feet from the ground. At two feet six inches high the circumference is twenty-two feet. In 1817 one half of the tree was killed by the burning of a house at close quarters; but the tree recovered, and the only trace remaining is a deep scar upon one side of the trunk. A lady of the vicinity used to tell of having seen in her childhood a pair of oxen running away over the tree which passed under the yoke, springing up behind them! This occurred only ninety-five years ago. This large tree is evidently in its old age, though still possessing considerable vigor.

The Sterling Elm is a notable tree in the pleasant village of Sharon, Connecticut, on the grounds of Mr. W. O. Wheeler. With a spread of 110 feet, the smallest girth of its trunk is seventeen feet. The trunk is very solid and cylindrical, and the tree is in full vigor. Sharon was first settled 150 years ago; and the position of this tree indicates that it was planted. This

was probably considerably after the settlement. I doubt whether this Elm exceeds a century in age; but it has already reached dimensions surpassed by very few.

The Deming Elm is another old tree in the same town. The smallest girth of its trunk, which is quite irregular, is sixteen feet three inches. Its total dimensions, however, are much inferior to the Sterling Elm's, and the tree is evidently in decadence. It was planted "in his youth" by the late Stephen Deming, and he was born in 1780.

Such instances as these indicate that Dr. Holmes' limit is unnecessarily wide, and that the normal age of this rapid growing tree is considerably within the popular estimate.

To show the rate of growth, an Elm by my own house, which is known to be scarcely, if at all, above fifty years old, may be mentioned. Its situation is very favorable—a warm, rich soil, within a few feet of a large spring. How commonly we find that great Elms have seated themselves near some perennial fountain or water-course, at least within reach of their courier roots! This Elm of half a century, with a trunk twenty feet to the limbs, measures in circumference at three feet high, and entirely above the spread of the roots, eight feet six inches.

Amenia, N. Y.

Myron B. Benton.

A Silva of New England.

To the Editor of GARDEN AND FOREST:

Sir.—The earliest Silva of New England is contained in the following lines, which may interest some of your readers. They were printed in 1670 in London in "A True, and Faithful Account of the chieftest Plantations of the English in America, to wit of Virginia, New England, Bermudus, Barbados." The name of the author does not appear, but the remarks which he adds upon the value and use of some of the New England trees, and of their fruits, are copied, with a few verbal changes, from Wood's well known "New England Prospect," published in 1634.

"Trees both on Hills and Plains in plenty be,
The long-liv' Oake, and mournful Cyprès Tree,
Sky-towering Pines, and Chefnuts coated rough,
The lafting Cedar, with the Walnut tough;
The Rofin-dropping Fir for Mafts in ufe,
The Boatmen feek for Oars, light, neat grown Sprufe;
The brittle Afh, the ever trembling Apfes,
The broad fpreed Elme, whose concave harbours Wafps;
The watry fpungy Alder good for nought,
Small Elder by th' Indian Fletchers fought,
The knotty Maple, pallid Birch, Hawthorns,
The Horn-bound Tree that to be cloven fcorns;
Which from the tender Vine oft takes his Spoufe,
Who twines imbracing arms about his Boughs;
Within this Indian Orchard Fruits be fome,
The ruddy Cherry and the jetty Plumb,
Snake murdering Hafel with fweet Saxafrage,
Whofe fpouts in Beer allayes hot Feavers rage,
The Diars Shumack, with more Trees there be,
That are both good for ufe, and rare to fee."

Recent Publications.

The Fern Flora of Canada. Descriptions of all the Native Ferns of the Dominion, with localities where they grow. By George Lawson, Ph.D., LL.D., F.I.C., F.R.S.C., McLeod Professor of Chemistry, Dalhousie University. Halifax, N. S.: A. & W. Mackinlay.

This is a small quarto of about thirty pages (pp. 221-251), and is evidently an appendix to some other work, perhaps a school Flora of the Dominion. Professor Lawson has paid much attention to Canadian Ferns for many years, and is well qualified to write about them. The book begins with about seven pages of a general account of the nature and structure of Ferns, given in simple style, such as would be easily understood by the children for whose use the treatise has been prepared. Then follow a synopsis of the genera, twenty-five in number, and a plate with illustrations of seventeen of them. An account of the species occupies the remaining twenty-one pages. The descriptions are clear and simple, and have the merit of originality, none of them, apparently, being borrowed from other authors. Professor Lawson seems to have adhered faithfully to the rule of priority in his choice of specific names, even going so far as to take up Oakes' MS. name of *Asplenium platyneuron* instead of *A. ebenenum*. But it is not certain, after all, that Linnæus had this plant in mind when he wrote the name *Acrostichum platyneuron*. Willdenow plainly says that Linnæus' synonymy was all wrong, and the only

specimen of this Fern in the Linnæan herbarium is marked *Polypodium auriculatum*. *Asplenium marinum* is still mentioned as a Canadian plant, although no one has claimed to have found it since Captain Kendal, and although Macoun and Burgess say that the crediting of this plant to New Brunswick "is now known to have been a mistake."

Struthiopteris is kept separate from Onoclea, perhaps well enough. *Aspidium* is replaced by *Polystichum* and *Lastrea*. *Athyrium* is separated from *Asplenium*, and *Dennstædia* is preferred to *Dicksonia* for *D. punctilobula*.

But, of course, Fern-students cannot be expected to agree in nomenclature any more than other botanists, and each one will continue to call species by whatever names he thinks preferable.

Exhibitions.

The Flower Show at Philadelphia.

THE Spring Exhibition of the Pennsylvania Horticultural Society, which was held last week, was very largely attended and in every way successful, although in some features it fell below the standard of previous years. The display of Roses, for example, was not strong as compared with former exhibitions. This, however, was no fault of the growers; but the effects of an unfavorable season were plainly visible. Nevertheless such flowers of Ulrich Brunner as those for which Edwin Lonsdale gained the first prize were well worth mention. Indeed, this variety was superior to all others shown here this year in the qualities which make a first-class Rose. Among other varieties, C. F. Evans showed the best blooms of Magna Charta, Mrs. John Laing, La France, Papa Gontier, The Bride and Merveille de Lyon. Joseph Heacock took the first prize for Perle des Jardins, Niphetos, W. F. Bennett and Sunset. Besides his prize for Ulrich Brunner, Edwin Lonsdale showed the finest blooms of Madame Hoste, Madame Cusin and Madame Gabriel Luizet. The display of Souvenir de Wootton was somewhat disappointing in view of the fact that \$300 in prizes were offered to successful competitors. John N. May, of Summit, New Jersey, Joseph Heacock, of Jenkintown, Pennsylvania, and Coles & Whitely, of Lansdowne, received the first, second and third prizes for this variety.

The display of Orchids in bloom was excellent, especially the collection of Pitcher & Manda, which included some eighty plants of *Cypripedium* and almost as many of other genera. A superb specimen of *Cypripedium Boxallii atratum* with thirty-two flowers was among the gems of this collection. Other noteworthy *Cypripediums* were *C. Selligerum* and its variety *majus*; Pitcher's variety of *C. Harrisianum*; *C. Curtisii*; *C. Lowii*; *C. Enanthum superbum* and some beautiful examples of the snow-white little *C. niveum*. Among the *Cymbidiums* was a good specimen or the dark-colored variety of *C. Lowianum*. A fine specimen of the white *Lycaste Skinneri*, and some choice plants of the fragrant little *Angracum Sanderianum* attracted much attention. David Emery, gardener to Charles Dissel, and Charles F. Evans also received prizes for Orchids.

The spring flowering bulbs were less abundant than usual, but more beautiful Hyacinths than those shown by Henry Surman are rarely seen. The immense Azaleas shown by Robert Wark, gardener to Mr. C. H. Clark; the great mass of *Astilbe Japonica* from Craig & Brother; the White Lilies contributed by C. D. Ball, W. K. Harris and J. W. Colflesh; the Cinerarias shown by Thomas Long; and Pitcher & Manda's group of Anthuriums, were attractive features of the exhibition.

The display of decorative or foliage plants was unusually good. It would be hard to find a better collection of specimen Ferns than those furnished by Thomas Long, gardener to A. J. Drexel. Every one was perfect. A *Gleichenia flabellata* nearly six feet across, *G. dichotoma* of more than half that diameter, *Polypodium aureum areolatum* and *Davallia pallida*, were among the best. Wm. Joyce, gardener to Miss M. L. Baldwin; Robert Wark, gardener to C. H. Clark, and David Lutz, showed fine groups of Palms, Ferns, Dracænas and other plants grown for decorative purposes, and special premiums were awarded to H. A. Dreer and Charles Dissel for collections of foliage plants and Orchids arranged for decorative effect.

One of the remarkable plants of the exhibition was a *Heli-conia aureo-striata* from the gardens of Mr. Drexel, which was shown for the first time in Philadelphia. Another was a plant of *Lilium Harrisii*, the stem of which separated into four branches about four inches from the ground. There were twenty-two buds on all the branches, but only half this number came to perfection. It was grown by Mr. C. D. Ball, of Holmesburg, Pennsylvania.

Notes.

Messrs. Henry Holt & Co. are about to publish an "Introduction to Systematic Botany," by Professor Charles E. Bessey, of the University of Nebraska, well known by the botanies which bear his name in the American Science Series.

The new edition of Darwin's famous "Naturalist's Voyage Around the World," which has just been issued by the Messrs. Appleton, is noteworthy as containing maps and 100 views of the places visited and described. These are chiefly from sketches taken on the spot by Mr. R. T. Pritchett, and greatly add to the interest of the book.

Two noted Australian nut-bearing trees, which have been tested at the University of California, are the *Grevillea annulata* and the *Macadamia ternata*. The latter is an extremely handsome Holly-leaved tree, but of slow growth until well established. It suffered from frost once, but is hardy at Niles. The former is quite tender at Berkeley, and not a success there.

Messrs. A. B. Seymour and F. S. Earle, of Cambridge, Massachusetts, announce the publication of a series of fascicles, under the name of "Economic Fungi," to illustrate the diseases of useful and noxious plants. Each issue is to have a distinctive character, and the first, which is now ready, treats of fifty species. The fascicles will be supplied either in book form or in loose sheets at the price, respectively, of \$3.50 and \$3.

The leaf-blight of Quince and Pear (*Entosporium maculatum*, Lev.) has of late years been increasing in our orchards and nurseries, causing leaves to fall and the fruit to crack. Professor Dudley, of Cornell University, reports that the disease can be controlled in all its stages by the copper solutions, so that the nurseryman or fruit-grower who sprays the leaves of his trees once in two or three weeks during the growing season will probably suffer no loss from this cause.

Consul Fay, writing to our State Department from Stettin, says that the potato crop is one of the best paying in Prussia, and the products therefrom—dextrine, potato-flour, starch, etc.—shipped to the United States from the port of Stettin during the last three months amounted to \$50,000. German manufacturers are at a loss to understand why we purchase these products abroad when we have such immense crops of corn, when it is realized that the percentage of dextrine in corn is fifty per cent. greater than in potatoes.

When the gum drawn from *Ficus elastica* was first discovered to possess economic value no one could have foreseen the myriad ways in which it would eventually be put to use. The most recent, perhaps, and certainly one of the most curious, is reported in the *Engineering and Mining Journal*, which says that experiments are being made in Germany with India rubber pavements. They were first laid on the carriage-road of a bridge at Linden, Hanover, and are now being tested in Berlin and Hamburg with "extremely satisfactory results. India rubber is said to combine the hardness of the stone pavement with the elasticity of asphalt, but does not become so slippery as asphalt."

At the Agricultural Exhibition which has just closed, in Paris, M. Millet, a horticulturist of Bourg-la-Reine, showed a really remarkable collection of Violets. The most interesting were Monsieur Arène, with large, dark violet, velvety flowers; Gloire de Bourg-la-Reine, with very ample, dark green foliage and extraordinarily large, pale blue flowers with rounded petals; Souvenir de Millet Père, with pale foliage and blue flowers; Armadine Millet, with leaves broadly margined with yellowish white and with small, dark blue flowers; Madame Millet, a variety of Parma with large flowers of a tender rose color, very agreeably perfumed, and Swanley White, another variety of Parma with white flowers.

It is well known that when our western districts were first settled the best woods were wasted or put to services for which inferior sorts would have answered, with no thought of their future possible value. This was notably the case with the wood of the Black Walnut, of which a recent writer in the *Commercial Advertiser* says: "Thousands of fine trees were cut down, burned or allowed to rot on the ground, or split up for old-fashioned rail-fences. Now buyers rummage every mile of territory in the state (Iowa) to find logs and put them on the cars to be carried thousands of miles across the ocean to be worked up into furniture for the adornment of European

palaces." It is said that last year between 1,200 and 1,500 car loads of old walnut logs were thus exported.

The Fuchsia, now one of the commonest of garden plants, was introduced into cultivation about a hundred years ago by Mr. James Lee, a nurseryman of Hammersmith, who saw a plant growing in the window of a sailor, who had brought it from the West Indies. The genus had, however, been discovered much earlier, as it was described in 1705 by Plumier, who named it for Leonard Fuchs, a Bavarian botanist of the sixteenth century. According to a writer in the *Revue de l'Horticulture Belge*, the species, or one of the species, known to Plumier was *Fuchsia triphylla*, which was subsequently lost sight of until re-discovered in 1884 on the Island of St. Domingo and sent to Kew for identification. Its flowers are a glowing cinnamon-red, and about an inch and a half in length.

The Eucharis mite (*Rhizoglyphus Robini*) occurs much more frequently on Hippeastrums than is commonly supposed. Mr. Veitch, in his recent essay on these plants, does not, however, recommend the destruction of all bulbs affected with this pest; on the contrary, he states that he has never seen a bulb so badly infested as to be incurable. Excessive watering, in Mr. Veitch's opinion, affords the conditions favorable to the increase of the mite and the destruction of the bulbs, which is only another way of saying, keep the bulbs from falling into weak health, and the mite will not hurt them, although it may be present. At Kew there are large bulbs of *H. aulicum*, which have been in the collection for years and have flowered annually notwithstanding undoubted evidences that the mite is upon them and has been there all along.

One of the most individual and interesting of the many admirable statues which adorn the streets and parks of Paris is Fremiet's "Jeanne d'Arc," in the Place des Pyramides. Nevertheless, after it had stood for a number of years, the sculptor was so dissatisfied with it that he prepared a new statue on the same general lines in the hope that he would be allowed to substitute it for the earlier one at his own expense. His request was refused, however, by the municipality, and if it is true, as recently stated, that the Fairmount Park Association has secured the new statue, they are to be congratulated upon the possession of a work of surpassing excellence and beauty. As shown in drawings that were published last summer in Paris, it preserves the poetic and delicate individuality of the original, while the changes made in the horse, the harness, the pose of the heroine's arm and the form of the standard she carries all seem distinct improvements.

Catalogues Received.

George Thurber.

THE death of Dr. George Thurber ends the career of the most accomplished horticultural writer America has produced. Dr. Thurber was born in Providence, Rhode Island, in 1821, and early became interested in botany in connection with pharmaceutical studies which he took up in preparation for his business as an apothecary, which he conducted in his native city. His love of plants, however, was strong, and brought him into relations with Dr. John Torrey, of this city, then the leader among American botanists and a man whose influence was widely felt. It changed entirely Thurber's career, and secured for him, in 1850, the position of naturalist, to which were added the duties of quartermaster and commissary, of the United States and Mexican Boundary Survey. He was attached to the headquarter's party under command of Mr. John Russell Bartlett, the principal commissioner for the United States, and was actively engaged during four years in exploring the natural products of the country between the Gulf of Mexico and the Pacific Ocean. These journeys extended to nearly five thousand miles, and carried the party into regions which were, at that time, entirely unknown, scientifically. Thurber "was indefatigable," to use Mr. Bartlett's words, "in his exertions to make thorough examinations and complete collections of everything belonging to his department." He discovered many new plants within the limits of the United States and in northern Mexico, where the party made several long and exceedingly arduous journeys. The most interesting of his new plants were published by Asa Gray ("Plantæ Novæ Thurberianæ") in 1854, the name of the discoverer being there commemorated in a new Hibiscus-like plant, *Thurberia thespesioides*, which he had found in Sonora in 1851.

Dr. Thurber, the duties of the Commission being completed, returned to this city and accepted a position in the Assay office, from which he resigned on account of political differences with the authorities, and devoted himself to chemical and botanical studies, lecturing on these subjects at the Cooper Union and before the New York College of Pharmacy. In 1859 he was chosen to the

Professorship of Botany and Horticulture in the Agricultural College of Michigan, a position which he held until 1863, when he became editor of the *American Agriculturist*, of this city. This place he filled with singular success for twenty-two years, when he was compelled, by failing health, to relinquish the active control of the paper, although he continued to contribute to its columns and give it the benefit of his counsel until within a few months of his death. Dr. Thurber's influence as editor of a widely read popular journal was great. His writing was characterized always by sound common sense based on exact knowledge of many subjects, and they did more in his time to elevate the standing of the agricultural and horticultural press of the country than the writings of any other man. He possessed a charming style and a rare facility for explaining the most complex subjects in clear and simple language. This gift made the "Doctor's Talks," which he contributed during many years to the *American Agriculturist*, and which were intended to instruct young people upon scientific subjects, models of their kind. Of horticultural matters he wrote out of a full knowledge, as his garden at Passaic, New Jersey, an experimental garden in the true sense of the word, was one of the most interesting in this country. In this garden he found the pleasures of his later years, and these pleasures he shared with the public through his "Notes from the Pines."

Dr. Thurber's editorial work was not confined to the columns of the *American Agriculturist*. The publishers of that journal were large publishers, also, of books relating to country life, and most of these passed under Dr. Thurber's critical eye, or, in some cases, were entirely rewritten by his hand. He published, in 1859, "American Weeds and Useful Plants," an enlarged and greatly improved edition of Darlington's "Agricultural Botany," which is still the standard work on the subject, and he contributed the articles upon botanical subjects to "Appleton's Cyclopædia." Dr. Thurber's predilections in botany were for what may be called agricultural botany. This led him to make a systematic study of Grasses, and his knowledge of these plants was unequaled for many years in the United States. It was his intention to prepare a monograph of American Grasses, but editorial duties and failing health, undermined by the hardships of the Mexican boundary, compelled him to abandon this undertaking, for which he was otherwise admirably equipped; and of late years he has been able to do little beyond occasional contributions to the press. His very last work, written almost on his death-bed, was published in this journal a few weeks ago.

Dr. Thurber was a man of great knowledge and of the broadest sympathies; kind, faithful and true, generous to a fault, simple in the ways of the world, and always more interested in the welfare of others than in advancing his own interests. His death removes an interesting and picturesque figure, and a man who will never be forgotten by his friends.

THE bill for the protection of forest-lands on the public domain, which was introduced in the House of Representatives by Mr. Dunnell, of Minnesota, embodies substantially the provisions which have been advocated in these columns—namely, the withdrawal of all government forest-land from sale and entry, and the temporary protection of such forests by the army until a competent Commission, appointed by the President, shall report a plan for their permanent administration. This bill goes before a sub-committee of the Public Lands Committee of the House, consisting of Hon. Lewis F. Watson, of Pennsylvania; Hon. Erastus D. Turner, of Kansas; Hon. Joseph M. Carey, of Wyoming, and Hon. John Quinn, of New York. The Law Committee of the Pennsylvania Forestry Association has issued a timely circular calling upon its members to write to any of the representatives on this Congressional sub-committee with whom they may be acquainted, and present such facts and arguments as may be at their command in favor of the passage of the Dunnell

bill. This is good counsel, and we trust that every one who reads this paragraph will promptly act upon it. Some of the bills which will come before this sub-committee are framed for the purpose of facilitating the destruction of the national forests, and they will not lack interested advocates; it is the part of public spirit to make use of every legitimate influence to oppose these pernicious measures and to hasten action by Congress for preserving and maintaining the remnants of the forest on the national domain.

The Parterre, Fontainebleau.

NO royal residence in France is more famous than Fontainebleau, partly because of the palace and the historical associations that cluster round it, and partly because of the beautiful neighboring forest, which, for ages, was the favorite hunting-ground of the court. There is no record of the foundation of the palace, but it was already ancient when Saint Louis, in the thirteenth century, added a tower, which was the only portion suffered to remain amid the reconstructions of François I. Peculiar interest attaches to these reconstructions, for, in order that they might be fittingly completed, the King summoned a number of celebrated artists from Italy and thus potently influenced the development of the art of the Renaissance in France. Henry IV. also added to the palace, and he doubled the size of the grounds, which, in the reign of Louis XIV., were radically remodeled by Le Nôtre. Between his day and ours there have been many alterations both within and without the palace, but the general aspect of the place still largely represents the ideals of the sixteenth and seventeenth centuries.

The gardens are divided into three portions—the Parterre, or garden proper; the English Garden, laid out in the "natural style" and bordered by a lake; and the private Jardin du Roi or Orangery. Our picture shows the Parterre, which is interesting as an example of modern taste in planting applied to an ancient design. Here we have not the so-called "French parterre," which, as recently described in these columns, consists of long beds thickly planted with masses of hardy flowers that are arranged with a care for form and color contrasts, but then allowed to grow in natural luxuriance. We have, instead, a succession of formal beds, such as are very familiar in America, but disposed in a more appropriate way than is often the case with us. From the regularity of all the lines of the design these beds do not seem too stiff and mechanical; and in a general view they do not make inharmonious spots, but blend into long strips of color which effectively relieve without disturbing the reposefulness of the wide lawns. In the picture we seem to read traces of the fact that larger beds, now turfed over, formerly occupied the centre of these lawns; and we feel sure it was well to do away with them.

Of course in our climate such a wide space so simply treated and quite devoid of shade would not be a very agreeable place of promenade in summer, while the grass would often be so burnt as to injure beauty in a distant view. But in the grayer, damper, cooler climate of northern Europe these objections do not hold, and the broad open Parterre is a welcome contrast to the informal English garden and to the adjacent park, the trees of which show in the background of our illustration. The main point we wish to emphasize is, however, that the formal flower beds which are so hideous and disturbing when introduced into a "natural" arrangement, may be entirely pleasing in a formal one. The fact is as true if, instead of a garden so extensive as this at Fontainebleau, we have one so small that even in our climate its openness would be no fault and its grass could easily be kept well watered. Lovers of such brilliant beds could use them to produce beauty instead of discord if they were willing to exchange the curving paths and carelessly grouped shrubs of their little grounds or front yards for straight paths and symmetrically arranged plantations.

Methods of Botanical Study.

FEW persons will take exception to the argument made in your columns in advocacy of botany as a study for the young. But there are different methods of study, and since the "laboratory method" has been criticised it may be well to outline the plan adopted by many successful teachers of the science.

The "laboratory men" place abundant materials within the reach of students, and with a few hints and suitable apparatus require them to proceed to make discoveries for themselves. They first observe, handle, dissect, compare and study

the specimens, and after this they begin to make some use of books. The "laboratory" method includes the study of gross anatomy of plants with the unaided eye or with a simple microscope, as well as plant physiology, where assistance is received from compound microscopes and other apparatus.

In the old-fashioned way the student was taught, or learned from books mainly, a large number of facts, names, systems of classification, etc. This plan is still extensively adopted, as we may infer from the following, taken from the opening paragraph of Wood's "Botanist and Florist," recently revised: "The proper season for the commencement of the study of botany in schools is late in winter, at the opening of the first session after New Year's. The class will thus be prepared beforehand, by a degree of acquaintance with first principles, for the analysis of the earliest spring-flowers." The plan above followed is dull work.

The old method places the pupils in front of a lecturer, who pours information into them, or questions them concerning lessons learned from a book. In the old method the students witness the play; in the new they begin at once to be the actors. To become a good botanist one must depend mainly on his own exertions, and become a self-made man. This depends little on the information imparted by the teacher, but largely on what the teacher induces his pupils to do for themselves. In the old way the pupil gains knowledge mainly; in the new, besides knowledge, he acquires method, confidence, power and enthusiasm.

The science of botany within thirty years has broadened to an astonishing extent. Now we have all that was ever of value to engage our attention in botany, and five times as much more. We still cling to systematic botany as essential, but cannot get along without the plant structure and physiology and the lower forms of plants which the microscope has revealed. This large expansion of the field has led to changes in methods, and we believe to improved methods of study.

The following, from President Eliot's last annual report to the Board of Overseers of Harvard University, is in point:

"During recent years every college teacher has been forced to answer anew the personal questions, what can I best teach, and how shall I teach it? Every man has really been obliged to take up new subjects and to treat them in new methods. There is not a single member of the faculty who is to-day teaching what he taught fifteen years ago as he then taught it. . . . Each teacher has had to recast his own work, each department repeatedly to modify and extend its series of courses."

The laboratory method claims to include a study of plants in the field, forest, prairie and ravine; their morphology, the great variety of ways in which pollen is carried from anther to stigma, the contrivances for keeping unwelcome guests from flowers, where they can be of no use to the plants, the plans by which some plants entice, entrap and feed on insects, the motions of plants, the climbing of roots, leaves, tendrils, the ways in which nature sows, distributes and plants seeds, and many other things not here mentioned.

Dr. Goodale, in "Guides to Science Teaching," says: "The pupil must earn his facts; they are to be placed within his reach, but not in his hands. The technical terms are not thrust upon the student; they are introduced only as they are needed."

I cannot refrain from quoting the following from Dr. Farrow. It is found in *Popular Science Monthly* for March, 1886:

"The position of the instructor is not an easy one. He is under constant restraint, as he must not tell the student, but must, if possible, make the student tell him, the structure of what lies before him. He is in the position of a boxing master who might easily floor his pupil by a single blow, but who must, by the exertion of great prudence and skill, contrive to let the pupil hit him. By a judicious series of questions, suggestions of possibilities or alternatives, the student may be kept in the right track and yet do all the work of advancing toward the truth himself.

"The most serious obstacle, it seems to me, is not so much that boys are not taught biology at school, as that they are not taught to observe, but are, on the other hand, taught to memorize text books, and to regard education as the acquiring of facts in the most rapid and easiest way.

"Patting one on the back and saying, 'Don't you see this?' and 'Don't you see that?' does not tend to produce a very robust mental development."

In the new botany, for which we are speaking a good word, we set pupils to studying plants before books. Before the first lesson each pupil is furnished or told where to procure some specimen for study. If it is winter, and flowers or growing plants cannot be had, give each a branch of a tree or shrub, which may be two feet long. The examination of these is

made during the usual time for preparing lessons, and not while the class is before the teacher. For the first recitation each is to tell what he has discovered. The specimens are not in sight during the recitation. In learning the lesson, books are not used; for if they are used, no books will contain a quarter of what the pupil may see for himself. If there is time, each member of the class is allowed a chance to mention anything not named by any of the rest. The pupils are not told what they can see for themselves. An effort is made to keep them working after something which they have not yet discovered. If two members disagree on any point, on the next day, after further study, they are requested to bring in all the proofs they can to sustain their different conclusions. Give other specimens for the next lesson, keep reviewing, and generalize as details and facts accumulate.

I like to give two species for a careful comparison. For example, naked or growing branches of Elms, Maples, Ashes, Oaks, Box-elders, Beeches, Poplars, Willows, Walnuts, Butternuts, Hawthorns, Cherries, Evergreens, and, in fact, any of our native or exotic trees and shrubs. Discoveries, very unexpected, are almost sure to reward a patient study of these objects. The teacher must not think this time wasted. No real progress can be made till the pupils begin to learn to see, and to learn to see they must keep trying to form the habit from the first, and to form the habit they should make the study of specimens the main thing, as they cannot acquire the habit by the study of books.

These hints could be much extended. After a few weeks, reviews may be made in connection with chapters in some book. I make it a rule to give pupils specimens for study and comparison regarding every chapter in Gray's Structural Botany, before the book lesson is studied. I place no stress on making these investigations in the order in which the chapters of a text book are arranged.

Free use is made of our botanic-garden, the crops in the vegetable-garden, fields and experiment station, and the thickets along the river. Special topics are often assigned, in which each student has to go many times to observe and record observations on his growing plant. I often go with them for this purpose. Illustrations by drawing are a prominent feature of the course from the very beginning.

Agricultural College, Mich.

W. J. Beal.

Exotic Palms in Florida.

OUR last great freeze came on Monday, March 17th, just forty-six years ahead of the time fixed by our weather prophets, and it affords a valuable, though most unwelcome, opportunity of testing the hardiness of our choice exotics.

My thermometer here, in latitude twenty-eight degrees forty minutes, registered a minimum of twenty-one degrees; my neighbor's, twenty-three degrees, in a more sheltered place, and other observers in the vicinity report all the way from nineteen to twenty-five degrees, the last temperature being where a cloud of smoke from burning woods had settled during the night. Young Orange-trees are mostly killed to the ground—many thousands of them, both in grove and nursery—and old trees lose all, or nearly all, their leaves. I know of a single instance where a tree ten inches in diameter is killed to the ground; but, as a rule, the trunks and branches of old trees are uninjured.

Oleanders lose all their leaves, and, perhaps, the smaller branches. A good many young Peach-trees and Rose-bushes are killed to the ground, but the majority escape with moderate injury. Half hardy shrubs, like Cattley Guavas, are often cut back half way; common Guavas, *Eugenia uniflora* (Cayenne Cherry or Pitanga), *E. jambos* (the Rose Apple) and *E. Ugni* (the Chilian Guava) are killed quite to the ground. Soap-trees (*Sapindus Saponaria*) lose their leaves only; but exotic Tecomas (*T. stans*, *T. Capense*, etc.), as well as Rose Geraniums, Hibiscuses and other common ornamental plants, will have to start anew from the level of the ground. The Tea Olive is untouched, and the common Jessamines (*J. revolutum*, *J. humile*, etc.) are a little cut back. *Araucaria excelsa* preserves its main stem, *A. Cunninghami* had to be cut off a foot from the ground, and *A. Cooki* was killed to the ground; both the latter had the protection of small lath-screens.

These instances show the exceptional severity of the weather, and it is gratifying to note what a large number of fine Palms escape serious injury amid the general destruction. Of course our native Palms are unhurt. Cabbage and Dwarf and Saw Palmettos, and an apparently undescribed species of Sabal, which replaces the Dwarf Palmetto (*S. Adansoni*) in dry scrub land of the Lake Region, are frost proof, as is also our Needle Palmetto (*R. hystris*).

The exotic Palms tabulated below as "Hardy" show no injury, or only a trace of frost bite. The "Half-hardy" lose from one-fourth to three-fourths of their foliage. Those of the third class were quite defoliated, and in some cases may, perhaps, be dead, though very few seem to have lost the central bud. In some cases the same name will appear under two headings; this shows that plants in different situations behaved differently. None of the species tabulated had any protection.

HARDY PALMS.—*Cocos Alphonsei*? *C. australis*, *C. australis argentea*, *C. Blumenavia*, *C. Bonneti* (two varieties), *C. campestris*, *C. coronata*, *C. Gartneri*, *C. mamillaris*, *C. Normanbyana*, *C. petraea*, *C. Romanzoffiana*, *C. speciosa*, *C. Yatai*, *C. sp.* (very glaucous, from Entre Rios); *Phoenix Canariensis*, *P. dactylifera*, *P. Leonensis*, *P. Natalensis*, No. 1; *P. Sahariensis picta nigra*, *P. Siamensis* (two varieties), *P. tenuis*, *Sabal dealbata*, *S. flabelliformis*? *S. Ghiesbreghtii*, *S. humilis*, *S. Mauritiiformis*, *S. Mexicana*, *S. Mocini*, *S. speciosa*, *S. umbraculifera*; *Chamaerops Indica*, var. *nigra*, *C. humilis* (in variety), *C. excelsa*, *Erythea armata* (glaucous), *E. edulis*; *Jubaea spectabilis*; *Washingtonia robusta*.

HALF-HARDY PALMS.—*Cocos botryophora*, *C. Datel*, *C. Guacuyule*, *C. Mikianiana*; *Phoenix acaulis dactylifera*, *P. farinifera*, *P. Leonensis*, *P. paludosa*, *P. rupicola*; *Sabal glaucescens*, *S. longifolia*, *S. princeps*; *Brahea dulcis*; *Livistona* (*Corypha*) *australis*; *Washingtonia filifera*.

PALMS WHICH CAN ENDURE BUT LITTLE FROST.—*Cocos capitata flexuosa* (this may be *Syagrus cocoides*), *C. Mikianiana*; *Phoenix cycadifolia*, *P. dactylifera* (from Lower California); *P. dumosa*, *P. Farinifera*, *P. glaucescens*, *P. humilis*, *P. Natalensis*, No. 2; *P. paludosa*, *P. pumila*, *P. reclinata*, *P. rupicola*, *P. Sahariensis picta nigra*, *P. sylvestris*? *P. tomentosa*, *P. Zanzibarensis*; *Acrocomia Totai* (unhurt at twenty-six degrees); *Phopalostylis* (*Areca*) *sapida*; *Livistona Sinensis* (*Latania Borbonica*); *Rhapis flabelliformis*.

None of the Palms here mentioned are injured by cold weather short of freezing, while a temperature of forty degrees, long continued, will kill many strictly tropical Palms.

The behavior of some Palms planted in the forest, having abundant shade and moisture, is interesting. An Orange-tree in such a situation lost every leaf like those fully exposed. So did *Areca sapida*, which endures light frosts, while *Rhapis vinifera* was only partly cut back and *Elæis Guineensis* was untouched; *Arenga saccharifera* retains half its leaves; *Latania Loddigesii* and *L. Commersoni* (*rubra vera*), *Glaziovina insignis* and *Phoenix sylvestris*? *P. cycadifolia* and *P. paludosa* are all unhurt. A *Dypsis* from Moritius loses but one tender leaf. *Caryota sobolifera* endured previous frosts and is now cut back, but a thrifty sucker from its base seems ready to replace it if necessary. *Seaforthia elegans* and four species of *Chamaedorea* and a small *Diplothemium candescens* lose every leaf, but are apparently alive; one *Geonoma elegans* is untouched, while others around it lose all their leaves, a small *Hyophorbe Verschaffelti*, usually tender, by some chance escapes altogether, while several plants of *Oreodoxa regia*, hitherto unhurt, lose every leaf.

A number of Orchids and small Tree Ferns were "naturalized" in the forest and endured the freeze fairly well without any protection except that of the forest itself.

Of those growing on trees, *Lalía anceps*, *L. autumnalis* and *L. majalis*, *Dendrobium nobile* and *Epidendrum cinnabarinum* are all unhurt, *Lalía purpurata* and *L. harpophylla* are somewhat nipped, and *Acropera Loddigesii*, *Chysis aurea*, *Lycaste sp.* and *Calia Baucrana* seem to be killed.

Of those treated as terrestrial and planted in leaf mould on the bank of a small stream, *Cypripedium insigne*, *C. barbatum* and *Dendrobium nobile* are unhurt. *Phajus maculatus*, *P. grandiflorus* and *Calogyne cristata* lose a portion of their leaves. *Sobralia macrantha* loses most but not all of its stalks and *Peristeria elata* (the "Flor del Espirito Santo") loses all its leaves. In the preliminary frost of March 3d, when the mercury reached twenty-six degrees, the *Peristeria* was untouched, though fronds of native Ferns were frozen and killed where they actually touched the leaves of this Orchid. As the thermometer showed twenty-one degrees during this last cold weather, the prospect of permanently naturalizing some choice Orchids in our woods is very encouraging.

Most of my Tree Ferns in similar situations were more or less hurt. Many of them had been recently planted out and the fronds grown under glass might be expected to be more tender than those produced out-of-doors. This proved to be the case, as the youngest fronds were the ones untouched with *Alsophila horrida* and *A. australis*, *Cibotium glaucum* and *C. regale* and *Dicksonia antarctica*.

Oviedo, Orange County, Fla.

Theodore L. Mead.

New or Little Known Plants.

Lycoris squamigera.*

THE plant which has been known to cultivators for several years, under the name of *Amaryllis Hallii*, of which a figure is now given on page 177, was brought originally from China by Dr. George R. Hall, of Bristol, Rhode Island, and has been distributed by the Messrs. Hovey, the Boston seedsmen. It appears to be the same as a rather rare Japanese species of *Lycoris* which was collected by the distinguished botanist, Maximowicz, of St. Petersburg, on the beach near Oyo, in the island of Kiusiu, and was first described by him. It was previously known to Siebold, however, as is shown by his herbarium, and a good figure of it is found under the name of *Natsu-dzuisen* in the illustrated Japanese work, "So-Mokou-Zousetsu" (vol. v., t. 59), by the native botanist Yokoussai. Dr. Hall had it in cultivation in his garden at Shanghai before 1860, and he states that it is often planted by the Chinese in their cemeteries. It may therefore be the same plant that is referred to by Mr. Baker as found in grave-yards at Ningpo and which he thinks will probably prove distinct. The present plant, however, accords very well with the descriptions of *L. squamigera*.

In appearance it strongly resembles the true *Amaryllis* (*A. Belladonna*). The bulb is large and globose, sending up in spring half a dozen bright green leaves, a foot and a half long by an inch broad. These leaves die down in late summer and are succeeded by the flower-scapes, which are nearly three feet high, stout and solid, bearing an umbel of four to seven fragrant flowers within two large bracts. The flowers, on pedicels nearly an inch long, are three or four inches long above the ovary, somewhat decurved, of a uniform light rose color shaded with a peculiar gray. The curving segments are much narrowed downward and unite to form a rather narrow tube nearly an inch long, in the throat of which, above the insertion of the stamens, is a row of short truncate scales. These scales are peculiar to this species and give to it its name. The very slender filaments and style are declined to one side and about as long as the petals.

The plant is of easy cultivation and proves to be perfectly hardy in our New England climate, in this respect differing from all others of its near allies so far as known, though there would seem to be no reason why the other three or four species of the genus, which are also natives of Japan and China, should not be equally hardy.

The genus *Lycoris* is closely related to *Amaryllis*, *Hippeastrum* and *Crinum*, all of which have flowers very much alike in general appearance. *Hippeastrum*, several species of which are cultivated under the name of *Amaryllis*, differs from *Lycoris* in its hollow stems and in its flattened instead of swollen black seeds. Its species all belong to the warmer parts of the American continent. The true *Amaryllis* belongs to South Africa, and, like *Crinum*, has large, round, green and fleshy seeds, and the fruit never opens by valves as in *Lycoris* and *Hippeastrum*. S. W.

Cultural Department.

The Comparative Liability of Trees to Disease.

ONE of the common questions asked by those intending to plant trees or shrubs, either for ornament or utility, is—Which kinds are least liable to disease? The same question is often considered by owners of large estates, railroad corporations, park commissioners or village improvement societies having for their object the obtaining of shade or the pleasing effect of foliage and flowers with the least possible expenditure of after-care and trouble. As generally understood the term "disease" includes the ravages caused by insects as well as those attributed to fungi, and to any other destructive effects of known or unknown origin, except such as are recognized to be the work of rodents or other vertebrate animals.

Any attempt to answer such questions must always be unsatisfactory because subject to many qualifications; and an answer applicable to one region may prove very misleading when applied elsewhere. In catalogues and works on

horticulture it is not unusual to find particular plants recommended as being free from certain diseases. Such observations may be approximately true, or they may merely represent the local experience of the observer biased by peculiar geographical, climatic or other conditions. An instance of this kind is afforded by the large English Gooseberry (varieties of *Ribes Uva-crispa*). When grown in this country the general experience is that the fruit is very liable to be destroyed by mildew, while occasionally gardens are found in which no injury of this nature is detected. Experiences of this kind are common with many plants, and when we say that particular species or varieties are not subject to disfigurement or destruction by disease, it must be remembered that all plants are liable to epidemics of which we may not now have any idea. Such an epidemic may be brought about either by introduction from abroad or by circumstances which suddenly become favorable to its rapid increase. The destruction or introduction of particular kinds of birds is known to have much to do with the increase or decrease of certain destructive insects; and climatic conditions and the vigor of the host-plants are important factors regulating the abundance or scarcity of injurious fungi. It often happens that the disease of a tree may be directly traced to some previous mechanical injury or lack of nourishment which first gave the parasites a foothold.

Many insects devour the foliage of a great variety of trees and other plants. The well known Fall Web-worm (*Hyphantria cunea*) and the polyphagous locusts are examples. Pests which feed so indiscriminately are more likely to be permanently troublesome than those which are known as monophagous, and which confine their attack to one species of plant, or at most to a particular genus. However, all such destroyers are occasionally subject to violent natural checks, and with fungi, a season of much injury may be followed by one or more of comparative freedom from attack. The following brief review of some of the hardy trees merely refers to the north-eastern portion of the United States and Canada.

It will be seen that very few are to be classed as in any degree safe from noxious diseases. It happens that the Magnolias, the first group of trees as classified in our botanies, is also the most remarkably free from injuries by any disfiguring diseases and particularly from attacks by insects. This seems to be true both of our native species which grow from Massachusetts to Florida and also of those exotic kinds in our gardens. Several species of insects are known to feed solely or occasionally on these trees and numerous fungi are recorded; but it is very rarely that the foliage of a Magnolia is noticeably affected. Thus it would seem that the Magnolias wherever hardy are among the best trees to select for ornamental planting where little after care is to be given. Compared with the Magnolias, the Tulip-tree has more insect-enemies. Chief among these is a scale insect reported as sometimes very injurious in the Western States, an aphid which occasionally hurts the appearance of the foliage, and a minute two-winged fly, recently noticed in these pages (vol. 2, p. 604) as disfiguring the leaves by causing brown spots in them. Yet the Tulip-tree is usually counted among those least liable to disease.

The liability of the Lindens to serious attacks by insects is too well known in some parts of New England to need referring to here. The Horse-Chestnut and the Buckeyes, and more particularly the Maples, have a long list of active enemies, but are usually much less liable to serious disfigurement than the Lindens and therefore they are better fitted to be planted as street shade trees and in parks. Fungi sometimes hurt the leaves, especially those of the Horse-Chestnut.

Two Asiatic trees, the Ailanthus and Phellodendron, have so far generally shown very slight liability to serious diseases in this country. Of the hardy trees belonging to the Pea Family, the Locust (*Robinia Pseudacacia*) seems the worst attacked. It is well known that the trunks and branches become sadly diseased by borers. On the other hand, the Honey-Locusts (*Gleditschia*) are, as a rule, remarkably free from unsightly disfigurement of foliage or disease of stems. The Kentucky Coffee-tree and the beautiful Yellow-wood (*Cladrastis lutea*) are even less subject to injury than the Honey Locust, and the Yellow-wood especially harbors very few insects. The Japanese Sophora does not appear to be quite so exempt.

The Wild Cherries, the Mountain Ashes and Hawthorns and other trees of the Rose Family are more or less subject to many of the same insects and fungi which infest the fruit trees of our gardens. The Wild Cherries in particular are preferred by some of the most obnoxious insects.

The Flowering Dogwood (*Cornus florida*) has the merit of being distasteful seemingly to many destructive insects, so that it usually retains unblemished foliage. Equally free from disease is the beautiful Tupelo (*Nyssa sylvatica*); but both it and

* *LYCORIS SQUAMIGERA*, Maximowicz in Engler's *Bot. Jahrbücher*, vi. 79 (1885); Baker, *Amaryllidaceæ*, 40.

Fig. 32.—*Lycoris squamigera*.—See page 176.

the Dogwood are the hosts of many species of fungi. Ash-trees serve as food for a number of common insects, but in isolated situations they appear to be less liable to serious destruction of foliage than Elms. Among the latter there seems

to be but little difference in the value of the different species in regard to freedom from injury. The American species appear to have slightly the advantage. Little of a damaging nature is recorded against the Sassafras and the Catalpas. The

handsome leaves of the latter are sometimes subject to disfiguring spots of as yet doubtful origin.

The Buttonwood-trees (*Platanus occidentalis*) in New England have, in recent years, obtained the reputation of having degenerated and become more liable to disease. For some reason, not well accounted for, the terminal shoots are often killed and the trees assume a tufted appearance. But few insects are known to attack the tree. The Walnuts and Hickories are among those trees which usually have comparatively well preserved foliage, even when that of many other kinds is destroyed. The Black Walnut seems especially exempt from serious insect attacks.

That the trees which are preyed upon by the largest number of species of insects and other parasites are not always the first to show disastrous effects, is well illustrated in the case of the Oaks. In Europe alone there have been recorded about 600 species of insects which live upon these noble trees, and a proportionately large number are probably to be found in this country; and Professor Farlow has stated* that "the list of fungi which grow on Oaks in the United States includes between five and six hundred species." Of course a large proportion of these parasites also live upon other kinds of plants, while many others are only found upon particular species of Oak. Such figures naturally cause surprise that these trees are able to support such a host of ravagers and yet maintain so fine an appearance as they usually do. On the whole, there seems to be little difference in the value of the various species when considered with regard to immunity from serious diseases; and, as no trees can ever fill their place, the Oaks must continue to be planted for ornament as well as timber.

Loudon states that the leaves of Birches are rarely subject to the attack of insects. Nevertheless there are about 300 species of insects known to live on these trees in Europe, and some of them are of quite a dangerous character. It is true, however, in New England, that the Birches seldom suffer severely. Occasionally they may be attacked by such general-feeding insects as the Fall Web-worm. In the vicinity of Boston, a few trees have been defoliated by one or two species of monophagous Saw-fly larvæ, and these, under favoring conditions, may sometimes become destructively abundant.

The Poplars (*Populus alba*, *P. monilifera* and *P. balsamifera*), so commonly planted in some of our cities, have lately acquired, especially in the region about Washington, a bad reputation on account of the destruction of the foliage by the Fall Web-worm and other insects; and dead trunks and limbs too often show the ravages of borers. The Willows are attacked by many of the same insects, and are, as a rule, hardly less subject to severe injury than the Poplars.

Among the conifers we find that the Pines and Spruces of our forests are, at irregular intervals, subject to extraordinary injury and destruction by borers and foliage-devouring larvæ. Fortunately there is less liability to such disasters in ornamental planting, where particular species of trees are usually few or comparatively isolated and insect-eating birds are more abundant than in the woods. Yet in isolated situations the tips of the branches of most of the Pines are often sadly injured by boring larvæ, and fungi are sometimes quite destructive. During the past season an almost universal disease, of uncertain origin, caused the outer ends of the leaves of the White Pines to become brown. The greatest deformity of the Spruces in cultivation is caused by a Hemipterous insect (*Chermes*), which produces large, cone-like swellings on the ends of the branches. The Colorado Spruce (*Picea pungens*) has so far seemed to escape this disease in New England. It does not infest the native and foreign species of Firs, which, when young and in vigorous health, rarely allow disease of any kind to become manifest.

The Junipers are sometimes subject to several hurtful fungi, among them the well known "Cedar Apples." South of New York the Red Cedar and the Arbor Vitæ are sometimes very much injured by the Bag-worm; but north of Massachusetts the Arbor Vitæ is usually one of the trees most free from disfigurement. In recent years the foliage of the Larches over a wide extent of country has been annually largely destroyed by the larvæ of a Saw-fly (*Nematus Erichsonii*), which is supposed to have been introduced from Europe, and which is the worst known enemy of this beautiful tree. The Japanese Larch (*Larix leptolepis*) at the Arnold Arboretum has not yet been touched by this Saw-fly, but the data are not sufficient to warrant the statement that the tree will not be attacked. The Hemlock is one of the most beautiful trees for ornamental planting, and it has few enemies. Sometimes the presence of Red Mites (*Tetranychus*) gives a

portion of the leaves a pale or dusty appearance, but vigorous, well branched, isolated trees are rarely otherwise injured. Our Cypress (*Taxodium distichum*) has no serious enemies recorded against it, and the Ginkgo has so far given a promise of being one of the kinds best suited to those who want trees which do not require to be diligently guarded against destroying foes.

Arnold Arboretum.

J. G. Jack.

Grapes for Family Use.

I HAVE just been asked to name ten or twelve of the best varieties of Grapes for family use to plant in the vicinity of Plainfield, New Jersey. The inquiry comes from a man who has lately moved into the country, but who still retains his business in New York and goes into the city every day. As this class increases every year a reply to the inquiry may be helpful to some of the readers of GARDEN AND FOREST.

It is difficult to give a general answer to such a question, not only because individual preferences vary as to the quality of the different Grapes, but because differences of soil and of location and of the adaptability of varieties to different conditions make an answer which is correct for one place almost worthless for another a few miles away. However, as the soil in the district mentioned is a light sandy loam I will frame my answer accordingly, although in my own heavier clay soil in Essex County I would still name the varieties which I give below.

For early black Grapes I would name, in the order of ripening, Moore's Early, Cottage, Worden and Concord. These are all hardy, vigorous growers and likely to succeed anywhere in the state. The first named I have not found quite as productive as the others, but its earliness compensates for any deficiency in this respect. The quality is very much like that of the Concord, the parent of all the others, while the Worden is the largest and best of them. For earlier kinds than the above I might name Champion and Eaton, but the former is too poor in quality, and the latter has not yet established its true position as a grape for table use.

For later black Grapes the following kinds among Rogers' hybrids are named in the order of the estimation in which I hold them: Wilder, Barry, Herbert, Aminia and Merrimac. These are all first-class in size, thick skinned, meaty, and of richer quality than the preceding and better keepers.

For red Grapes I name Brighton, Delaware, Lindley (Rogers' 9), Agawam (Rogers' 15) and Berckmans. Of these, Delaware and Berckmans are among Grapes what the Seckel and Dana's Hovey are among Pears, small and not vigorous growers, but of first quality. The strongest grower is Agawam, a thick skinned, aromatic, musky-flavored grape, much admired by some and equally disliked by others. It is liable to set poorly, and the Lindley, equal to any in quality, has the same defect. The Brighton never fails to satisfy the most exacting taste, even if not fully ripe.

For white Grapes I name Lady and Martha first, because of their earliness. The latter is the more vigorous grower, while the former has the larger berry and is better in quality, but it wastes very soon after ripening, often before, and the clusters of both are small. Following these comes the Niagara, a larger and far better Grape in every respect; in fact, in my experience, it is the only white Grape I have that is worth the ground it occupies. Pocklington, so highly praised in some sections, is with me a failure in every way. Empire State and Duchess, while of better quality than Niagara, have berries only half as large and are so uncertain that I can only recommend them as an experiment. Lady Washington makes a fine cluster, but it is too late to be depended on in this latitude. Moore's Diamond and Hayes are as yet new—that is, they have not been cultivated long enough to make their good and bad qualities apparent.

I might mention several more in all classes that have some desirable qualities, but the list is large enough to select a dozen varieties from. Still it represents an individual opinion merely and a consensus of opinions gathered from a larger area may be more satisfactory. The New Jersey State Agricultural Society at its annual meeting six years ago voted on a selection of the best six varieties of Grapes. Ten red Grapes were named and eight each of white and black. The four of each color receiving the highest vote were, in the order named: Red: Brighton, Jefferson, Delaware and Wyoming Red; white: Pocklington, Duchess, Lady Washington and Lady; black: Concord, Worden, Moore's Early and Wilder. This vote was based on their value for general use, which included their value as market Grapes. Some kinds named were new and the desire to sell the vines probably influenced some votes. Some members, too, had no experience with all the kinds

*Vice-President's Address, Section F, *Proc. A. A. S.*, vol. XXXVI., 1887.

named. At that time Jefferson, Pocklington and Duchess had a fictitious reputation, gained by much advertising. I myself considered the Jefferson a Grape of great promise. Now I would like to change every vine I have. The true value of a really good Grape is not established in three or four years. The Worden, for instance, has been three times as long in obtaining its present standing. Four years later the same Society, balloting for the three best Grapes for general use, one of each color, decided in favor of the Brighton, red; Worden, black; and Niagara, white; and few Grape-growers in the state would to-day make any alteration in the list. The amateur who demands grapes of the highest quality, though fewer of them, and is willing to take extra care to obtain them, might need another list embracing the best of those named above and a few not mentioned here; but for the great majority of the people the list will give entire satisfaction and all the varieties can be grown with ordinary care.

E. Williams.

garden, which are, nevertheless, as unknown in horticulture as the Stapelias.

The objections urged against the admission of Stapelias into the garden are: (1) that most of them have flowers which smell disagreeably; (2) that they are, as a rule, dingy and unattractive in color; (3) that they are not easily kept in health in the garden. With regard to the first I am afraid that nothing can be said in palliation of the unpleasantness of the odor, except that it is not obtrusive, and people need not smell it unless they like. But both the first and second objections are of small account when weighed in the balance against what can be said in favor of these plants. Their flowers are large, they are often produced in abundance, rarely failing if the plants are in anything like health. In form the flowers are most remarkable, in structure they are full of interest for the botanist, whilst the colors, although quiet, are not wanting in attractiveness, being, as a rule, a mixture of yellow and purple-brown. They cannot be used in the making up of bouquets, nor would

The Parterre, Fontainebleau.—See page 174.

Stapelias.

IN the March number of *Hooker's Icones Plantarum*, Mr. N. E. Brown, of the Kew Herbarium, figures and describes twenty-nine species of Stapelia and allied genera; he also adds in a supplemental chapter some interesting notes on Stapelias in general, and those collected by Sir Henry Barkly when Governor of the Cape of Good Hope in particular. The plants figured in the *Icones* are not, as a rule, of any horticultural interest, but amongst these Stapelias are some which are already known in cultivation, and others which, in our opinion, deserve to become generally known and grown.

Stapelias, however, receive next to no notice from horticulturists; indeed, one might safely say that the number of gardens in which they are grown and the number of gardeners who know anything about them might be counted on one's fingers. To most people this will look like conclusive evidence of the worthlessness, in a garden sense, of all Stapelias. This is true only to a certain extent. It would not be difficult to name many plants of undoubted beauty and fitness for the

any but the eccentric think of wearing one in his button-hole. But there is, or should be, a place in the garden for the anomalous, the strange and the wonderful amongst plants as well as for the pretty, the gaudy and the fragrant. The Titanic *Amorphophallus*, which last year created so much excitement amongst horticulturists as well as botanists, is not a plant to grow "for cut-flower purposes." There are many Orchids, too, of even less beauty and interest than Stapelias, but which find a place in almost every collection. The horticulturist who failed to see anything to admire and long for in *S. gigantea*, with its huge, shaggy star a foot across, and colored yellow with brown blotches, must have a very narrow and unenviable taste for flowers. There are dozens of species of Stapelia with flowers as interesting if not quite so large as this giant of the genus.

The odor was designed by nature to serve the purpose of the plant, man's fastidious senses not being taken into account. Insects are needed to bring about fertilization in Stapelias and that it attracts them is evident enough even here, where flies visit them in large numbers to deposit their ova. Probably,

also, the putrid odor of the flowers is intended to protect the plants from animals, which, if it were not for the smell, might eat them. It is remarkable that whilst the native animals in Africa avoid *Stapelias*, the introduced sheep and goats eat them, and in those parts of the colony where these animals are most abundant the *Stapelias* have been almost exterminated. Apparently the "foreign" animals are not to be deceived by the smell. Something analogous to this is seen in the fruit of the Durian, the smell of which is detestable whilst the flavor is delightful.

Stapelias have long been cultivated at Kew and in a few other gardens in England. Mr. Brown himself has a good collection of them, and there are several amateurs who make *Stapelias* their specialty. In 1811 the Kew collection contained no less than forty-four species, the number of *Orchids* cultivated at that time being only thirty-seven. In 1868 about eighty species had been or were in cultivation in England. Between these two periods richly illustrated monographs and treatises on these plants and their allies were published by Masson, Jacquin, Haworth, etc. In the *Botanical Magazine* alone between thirty and forty species are figured, all from plants cultivated at Kew. At the present time close upon a hundred species are represented by living plants at Kew. Two of the most wonderful—namely, *Hoodia Barklyi* and *H. Bainii*—flowered here about ten years ago. This genus is, however, difficult to keep. *Decabelone*, *Huernia*, *Duvalia* and *Bouceirosia*, all closely related to *Stapelia*, and all equally interesting, are in cultivation at Kew and elsewhere.

Mr. Brown's collection is accommodated in a small greenhouse attached to his dwelling, and his success in the management of these plants has been so marked, whilst the treatment he follows is so easy of imitation, that I quote what he says on the question of cultivation:

"One interesting feature connected with *Stapelias* is the vitality of their seeds and the rapidity with which they germinate. When sown in moist, sandy soil, and placed in a greenhouse heated in summer only by the sun's rays, the night temperature going down to sixty degrees Fahrenheit, or lower, they germinate in less than forty-eight hours. Most of them are comparatively hardy, and under shelter, if the soil is kept dry, will stand a succession of slight frosts of from one to three degrees Fahrenheit, and some will endure as much as eight degrees of frost without injury, if not continued for more than a few hours. I have many plants now living, which I have cultivated for sixteen or eighteen years, that almost every winter have been subjected to a slight amount of frost during severe weather."

Where available, I would recommend the following treatment as better even than that described by Mr. Brown: Summer temperature, minimum, sixty degrees, with exposure to all sunshine. Whilst growing these plants require as much water as ordinary pot plants; they thrive when planted in light sandy loam, well drained. In winter the temperature should not fall below forty-five degrees, and the atmosphere about the plants should be kept as dry as possible. They do not require any water at the roots from November until about the end of March. Should the plants rot at the base the decayed parts must be cut away and the stems must be laid upon sandy soil. *S. gigantea* may be grown in a moist stove all the year round. Seeds of *Stapelias* may be obtained from Continental nurserymen. Mr. Hanbury has a large collection of these plants in his garden at Mentone. Professor Todaro, in the Palermo Botanic Gardens, also grows a considerable number of them.

Kew.

W. Watson.

Orchid Notes.

Lycaste aromatica.—This species may not possess sufficient merit to rank among the most handsome *Lycastes*. It is, nevertheless, a very desirable one, and worthy of the gardener's attention on account of its free habit and large fragrant flowers, which possess the additional recommendation of appearing in great numbers during the dull months of December and January.

It was first introduced from Mexico in 1824 by Lord Napier, and since that time has passed through the hands of botanists under the names of *Colax aromaticus* and *Maxillaria aromatica* until Dr. Lindley consigned it to the genus in which it now stands. From a structural point of view the flowers of *Maxillaria* and *Lycaste* resemble each other very much; hence in gardens many *Lycastes* are known as *Maxillarias*, and *vice versa*. One of the easiest means to distinguish these two genera is that *Lycastes* always have thin, plicate leaves, while *Maxillarias* are recognized by their stiff, flattish leaves, traversed by three to five strong nerves.

Lycaste aromatica has deep green, ovoid pseudo-bulbs, measuring from three to five inches long and becoming more or less angled with age. Three or four oblanceolate, plicate leaves, a foot or more in length, are borne on the summit of each pseudo-bulb, from the base of which spring the slender one-flowered scapes six to eight inches long, having at each node (there are usually four or five) a large dark brown spatheaceous bract. As many as twenty flowers, each about three inches across, are often produced from one pseudo-bulb, and, owing to the olive-green color of the broadly ovate, acute sepals and the bright cadmium-yellow of the smaller erect petals, they present a very striking appearance to the surrounding plants. The lip is three-lobed and colored like the petals, with the addition of several dark red spots at the base and a deeper yellow raised callus on the disc. There is a variety known in gardens as *Punctata*, which may be readily distinguished by having (on the lower portion of the petals) several blood-red blotches, similar to those on the base of the lip.

This *Lycaste* may be grown either in pots or baskets in the usual mixture of fibrous peat and sphagnum. In winter the temperature may range from sixty to sixty-five degrees, Fahr., gradually rising to about ten degrees higher in the summer months. Growth begins in spring and continues until the end of autumn, when the pseudo-bulbs begin to ripen, after which they shed their leaves and produce their flower-scapes. Plenty of water may be given during the growing period, but, as the time of flowering approaches, less and less will suffice. When the blooms have all vanished, the plants require a rest of a month or two, during which time very little is necessary—indeed, only just sufficient to prevent the pseudo-bulbs from shriveling.

Odontoglossum triumphans.—From February until the end of April this is one of the most conspicuous species of the genus. It is usually called a handsome species, and deservedly so, on account of its large, showy flowers, which individually measure over three inches across. From eight to ten is the usual number, borne on an arching scape, two to three feet long. The oblong-acute sepals and the broader petals, with erose or irregularly-toothed margins, are golden yellow, the former having a few large chestnut-brown blotches, the latter being decorated with similar, but smaller and more numerous, blotches. The blade of the lip, which is ovate or cordate-acuminate, with denticulate margins, is folded at the tip, and has a large deep brown blotch on the anterior portion, bordered by a more or less narrow yellow margin, while the lower portion is creamy white, sometimes tinged with yellow, and furnished with a forked, elevated white crest, on each side of which are shorter teeth. The column is over an inch long, pale green at the base, passing into pure white upward, and having on each side of the anther a large, slightly toothed, brownish wing.

O. triumphans is indigenous to the mountains of Colombia, where it grows at an altitude of 5,000 to 10,000 feet above sea level. It was first discovered about 1842 by M. Linden, near Pamplona, and some years later by Warscewicz. The latter, however, thought it was *O. Hallii*, and sent it to Europe as such, and this caused confusion between the two species for some time.

Plants of this species should be grown in a cool house—that is, one the temperature of which in winter varies from forty-five to fifty-five degrees Fahrenheit, rising a few degrees more in the summer months. As much diffused light as possible should be given, and the atmosphere should always be kept moist by means of damping the floors and sides of the house. During growth plenty of water may be given, and when the bulbs are getting ripe as much air as possible should be given so as to assist in the process.

St. Albans.

John Weathers.

Andromeda floribunda.—The mild winter has not brought this beautiful Evergreen into flower much before its usual time. It is just opening its first flowers now, March 25th, not much over a week ahead of last spring. There are so few good broad-leaved Evergreens that will thrive here, that this one is valuable on that account, aside from its great beauty. The small panicles of flower-buds are formed in the autumn, and are usually so numerous as to almost hide the leaves. In this condition they are very pretty, and it is not uncommon for passers-by in the winter to consider the shrub in full flower. A shady place protected by larger shrubs is suitable for this *Andromeda*, and I find a well drained, light soil to suit it well. In such a place it ripens its wood well, and this has a great deal to do with the question of hardiness.

Cercidiphyllum Japonicum.—I have marked this Japanese tree growing in many situations and find that it does the best in

deep, rich soil. The foliage when the tree is in ordinary situations is not over dense, and when on dryish ground it is quite thin. It is only when in deep soil that the great beauty of the tree is developed. It is then that the different colors of the foliage and leaf stalks are best displayed. The leaves are heart-shaped, dark green above and silvery green beneath, while the leaf stalks and veins are of a dark red. It has a well formed pyramidal habit. I am not aware that any trees have flowered as yet in this country. Seeds, however, can be imported which germinate readily, so that the slower way of layering and rooting cuttings will not be necessary.

Germantown, Pa.

Joseph Meehan.

Foxgloves.—It is not generally known that *Digitalis purpurea* and *D. lutea* (*ambigua*) force well. By potting good plants in ten-inch pots during the autumn, and by keeping them in a frost-proof pit, well lighted and aired when the weather permits it, they grow a little all winter, and come nicely into bloom by the first of May. Along with these appear Canterbury Bells and *Spiraea palmata* if treated in the same way. Add to the above a few plants of *Astilbe Japonica* or *Deutzia gracilis* and a very charming group can be formed. For vases or ornamental jars Auriculas and *Viola cornuta* Perfection, can be used with good effect until the time comes for ordinary summer-blooming plants.

Japanese Anemones.—For entrance-steps, porch or piazza decoration few plants excel well-grown specimens of *Anemone Japonica*. Ours are grown in twelve-inch pots, started in a frame during March, which advances them sufficiently in this latitude to bloom toward the end of September. Further south this would be unnecessary. We place five to six strong crowns in each pot, in good loam. As soon as the flower-stems appear in August liquid manure is given. Abundance of water is essential throughout the season; just sufficient staking is done to get good specimens. The best varieties are the white Honoring Joubert and the hybrid Pink.

H.

Wellesley, Mass.

Perpetual Carnations.—Carnations to flower in the open ground this summer should be planted early in this latitude—any time after the 10th of April if they have been growing in a cool place. Carnations are better without fire-heat at this season. It is important that the soil in which they are to be planted be rich in potash, and a liberal dressing of wood ashes is, perhaps, the best means of supplying this element. If the plants are ordinary spring-struck cuttings they should be planted about a foot apart each way; plants that have been wintered over in five-inch pots require more room, and, of course, give more flowers; yet, if the same amount of money is expended in small plants, the additional number should produce the same amount of bloom. The varieties of Carnations are so numerous, and so large a proportion of them are excellent, that it is hardly worth while to name a select list. Unfortunately there are but very few thoroughly hardy varieties of the class known as Border Carnations. Seedling plants will go through the first winter safely, as a rule; afterward, however, whether the plants are layered or stock is obtained by cuttings, the losses are heavy and the plants badly crippled. Unfortunately, we cannot grow the Clove Carnations here as they are grown in England, and where they are among the most satisfactory of garden plants.

Pearl River, N. Y.

John Thorpe.

Correspondence.

An American Arboretum in Germany.

To the Editor of GARDEN AND FOREST:

Sir.—It may interest your readers to hear something of an Arboretum formed by a distinguished German horticulturist, Dr. G. Dieck, in northern Germany, on that great level plain which sinks gradually toward the North Sea, where the winters are rigorous and the summer climate is often marked by excessive droughts. It is a severe climate, of course, for delicate plants, but the more difficult it is to form a collection, the greater the honor attached to it. Plants which can support a climate like that of northern Germany have passed, so to speak, a severe examination; and can therefore be planted in regions of less rigorous climates without danger of their succumbing to the first exceptionally severe winter, as is often the case with plants propagated in a mild climate or in an exceedingly rich soil.

Dr. Dieck's Arboretum, situated not far from Miersberg, on the line from Halle and Leipsic, in the village of Zoeschen, is rich in trees and shrubs from America, and especially in those of the remote and still little explored regions of the north-west

coast. Dr. Dieck, at a considerable sacrifice, sent recently several intelligent collectors into the northern part of Oregon, Washington and British Columbia to explore the rich Cascade Mountains and those of the Fraser River, and his Arboretum now contains a number of rare plants which would be looked for in vain in the richest gardens of the United States. The special merit of Dr. Dieck's methods is to have had seeds of trees, especially of conifers, of an extended north and south range gathered at the most northern or the most exposed station where the particular species grows, in order to make sure, if possible, that the seedlings would be able to resist the climate of the eastern states and of Europe.

Dr. Dieck explains in his Catalogue that all his plants are at the free disposition, gratuitously, if necessary, of botanists who may need them for scientific investigation; secondly, he offers them to botanical gardens and other scientific institutions, and also to private collections, if these have any scientific character; thirdly, they are put in commerce. To have an idea of the value of the plants Dr. Dieck has obtained from the Pacific coast, it is only necessary to examine the list of 120 species, mostly newly introduced, contained in the supplement of his Catalogue for September, 1889. I will add, in passing, that this list contains, also, all the varieties of Roses used in Turkey and Asia Minor in the manufacture of ottar of Roses, which Dr. Dieck has had collected in their native countries. But to return to the novelties from the Pacific coast contained in Dr. Dieck's Catalogue, where are found *Acer glabrum* in three varieties, *Alnus rhombifolia*, *Rhododendron albiflorum*, the beautiful Alpine Rose of the Cascades; *Menziesia glabella*, and *M. ferruginea*, *Celtis reticulata*, *Fendlera rupicola*, *Jamesia Americana*, *Fatsia horrida*, that beautiful Aralia of the Columbia River, which is hardy in our coldest climate; *Lonicera flavescent*, a new species from the Cascades, a new *Opuntia* from the Fraser River, *Pinus ponderosa scopulorum*, the dwarf Alpine form of the Yellow Pine, *Pachystigma myrsinites*, a pretty evergreen shrub from the cold region of the Columbia, the equal of the Japanese *Euonymus*; *Pentstemon Menziesii*, var. *Scouleri*; *Populus trichocarpa*, an elegant Poplar-tree; *Quercus agrifolia*, a semi-evergreen California species; *Rhus aromatica trilobata*, *Rosa Engelmanni*, which is probably a variety of *R. acicularis*; *Rubus ursinus*, *Sambucus arborescens*, a good and very beautiful species of vigorous growth, and not a variety of *S. racemosa*. There is a collection, too, of fourteen Willows from the mountains of the Pacific, which probably no one has cultivated before; on account of its beauty, *Salix tristis*, var. *pallida*, is worthy of mention, and so are *S. Barclayi*, *S. Hookeriana*, and the new *S. Flogeriana*, an ally of *S. pyrolaefolia* of Siberia, an Alpine species with stems spreading on the ground like a green sod over which the roller has just passed; *Spiraea betulifolia* and *S. corymbosa* in dwarf Alpine forms; *Symphoricarpos Floyeri*, *S. acutus*, and two new found varieties, one of which, *S. pauciflorus*, makes a compact little Alpine shrub.

I suggest to all botanists or lovers of trees who happen to be in northern Europe to stop and see this Arboretum and its enthusiastic creator; they will find there much to interest and instruct them. Dr. Dieck, and this is in my eyes his principal merit, does not imitate a great number of commercial cultivators, who only devote themselves to plants which find ready sale. On the contrary, his passion is for difficult genera, often the "common things" of amateurs, which have only a purely scientific interest. For example, he has brought together 350 forms of Wild Roses, and the astonishing number of nearly 450 forms of *Salix*. To increase his *Salicetum* he stops at nothing, and I permit myself in the interest of science to beg the botanists of the United States, who are in a position to procure rare or curious forms of Willows, to send them to Dr. Dieck, whose address is simply Arboretum, Zoeschen, near Miersberg, Germany. Cuttings and plants can be sent easily and cheaply by sample post.

H. Christ.

Bale, Germany.

[Nearly all the plants mentioned as novelties by Dr. Christ have been cultivated for years in the United States. Some of them, like *Rhododendron albiflorum* and *Pachystigma*, are difficult to manage, and the right way to cultivate them successfully has not been discovered yet. The handsome Aralia of the north-west has refused, too, to remain alive for any length of time in gardens. There are still many North American plants to introduce into cultivation, and a few good ones, and the more people there are who make collections of our plants the better. We venture to suggest, however, that some knowledge of what American gardens contain would be useful information to

any one sending out expensive expeditions to collect American plants; and we must protest against the publication in a trade catalogue of new names of scientific appearance for plants which may or may not be undescribed. American plants, and especially those which are in cultivation, are weighed down by a hopeless load of synonyms, and now if this load is to be increased and plants are to be scattered over Europe under inadequately published names, American botanists may have some cause to regret Dr. Dieck's zeal and enthusiasm in increasing his Arboretum.—Ed.]

Common Names for Plants.

To the Editor of GARDEN AND FOREST :

Sir.—In your recent editorial entitled "Botany for Young People," there is one point that, in my judgment, might have received more consideration.

Any one who has paid attention to the so-called "common names" of plants must have been struck with the fact that in the majority of cases such names are not common at all, but are rather names that have been coined by botanists themselves, or names used by a greater or less number of flower-lovers to designate the plant in question. The fact cannot be ignored that a great many people do not accept these common names, but adopt instead local names of their own, names varying in different parts of the country, and expressing the native feeling of the locality toward each particular plant, rather than a common feeling of the whole area over which it is found. Thus there may be dozens of common names for each plant, and flower-lovers from different parts of the country may refer to a plant by very different names, and be unable to discover, except by much explanation, that they are speaking of the very same thing.

The whole subject of the popular or common names of plants is one of the greatest interest. The local name of the plant is apt to be, as I have pointed out, the expression of the feeling of the locality which the plant excites. Therefore it is obvious that dull and untrained observation will find in a plant many false points of resemblance and many qualities that have no existence, and deduce from these a local name that absolutely misrepresents its true nature. For example, the early settlers were naturally keen to discover likenesses between the strange plants of their new home and the familiar plants of the old home left behind. As a result, many of our plants to-day bear names absolutely misleading and erroneous. There may have been, indeed, a good excuse for all this years ago; but can we say that to-day we have a right, not only to use these wrongly given names, but to teach them to our children in preference to names that are more correct?

It seems to me that the advocates of common names are every whit as tyrannical in their requirements as the advocates of strict botanical nomenclature. If a common name is to mean anything it must convey the impression of one plant and one plant only; or, at the most, one genus and one genus only, to the hearer. Now, in such a case what are we to do with all the local names of the same plant? Must we not decree that they should yield to some better recognized popular name, if our common name is to mean anything? This being so, why is there any objection to using the scientific name as being most generally recognized and most accurate? As an illustration, let me name a case already mentioned. Every one knows the pretty *Houstonia*, and no one, I think, finds the Latin name difficult to learn or awkward to pronounce. I was always taught to call it *Houstonia*, and to bear in mind that it was *Houstonia cærulea*, whether I needed to use its specific name or not. Now, the writer in *Saint Nicholas* says it is "simpler to call the pretty things Bluets." Well, perhaps it is "simpler," if any one by an exertion of will power refuses to learn or say *Houstonia*—but does the name identify the plant? In my experience I have found for one person who called the flower Bluets, half a dozen who called it Innocence; and, furthermore, have heard at least the names Spring Beauty, Day's Eye and Eyebright applied to this very plant in different localities. All three of the names last mentioned belong properly to other plants, so perhaps the illustration needs no further comment.

It seems to me the real question, therefore, is, whether it is better to use fixed Latin names or fixed common names in *lingua vernacula* for our plants. I do not think any reasonable person can for a moment doubt what the answer should be. The Latin scientific name is recognized the world over, the "common" name, as a rule, only in the sense of being local.

Now, if our children are to be taught the names of plants, is it common sense to teach them the name that is likely to be of the least use to them, in preference to a name that can always be accurately used the world over? Of course I admit that "no hard and fast line can be drawn between the two classes of names;" for every language will have its own popular names for plants, and may adapt the Latin names more or less to its own form. Such common names have their own value, and do not detract in any way from the argument.

I have said nothing as to the vexed subject of differences in scientific botanical nomenclature, and for obvious reasons cannot enter on it here. Some changes in scientific nomenclature are necessary for scientific accuracy, and to express the advances and readjustments of our best knowledge of systematic botany, while other changes are made, whether rightly or wrongly, for the purpose of establishing a uniform system of nomenclature. Whatever may be the views of particular botanists on these matters, the tendency is toward the greatest scientific accuracy of classification and the most uniform system of nomenclature—a tendency that no one can claim exists anywhere in the labors of those who tell us that the common names of plants are to be taught and used in preference to the Latin names that sooner or later every lover of flowers must adopt.

Boston.

Edward L. Rand.

Notes on a Few Plants in West Virginia.

To the Editor of GARDEN AND FOREST :

Sir.—The *Trilliums* (*T. grandiflorum* and *T. erectum*) in this region are especially luxuriant and abundant, and often afford specimens nearly twice the size of the common type. The last season I met with a clump of the white species, consisting of four stout stems, measuring twenty inches to two feet in height, and with leaves and flowers corresponding in size. Of the purple species, which is scarcely less common, the flowers will measure uniformly two inches and a half or three inches across, or nearly double that given by some botanists. Do not these facts suggest the capabilities of these beautiful plants, and the hope that a race might be secured larger and superior to any yet seen in cultivation?

The Pennsylvania *Anemone*, familiar to most observers, is another common plant in low, wet grounds, and of a specially vigorous growth. This, with its large white, waxy flowers, is always an attractive plant, but in many specimens as they grow here, and possibly elsewhere, although I have never seen attention called to it, the upper leaves (composing the involucre) are most beautifully margined with brown, which, if it could be reproduced in cultivation, as in the more distinctly marked specimens, would add much to its value as an ornamental plant.

Valeriana pauciflora, which Gray notes as rare or local, is here found in rather frequent, though always in restricted or sparse colonies. With the singularly long and slender tube of the pale purple corolla, and the rather odd-looking (pinnately divided) leaf by reason of the comparatively large terminal leaflet, this herb will claim the interest of most observers.

Another plant which both Gray and Wood note as rare, is here abundant, covering large areas in shaded ravines—namely, *Cedronella cordata*. In habit and appearance this is suggestive of the Ground Ivy (*Nepeta glechoma*), to which it is nearly related; it is, however, a handsomer species, with larger leaves and flowers, the latter being fully an inch long, and it would, doubtless, make a desirable plant for rock-work.

The Crimson Balm or Bergamot (*Monarda didyma*), sometimes cultivated and well known for the intense coloring of its flowers and as a fragrant Mint, botanists tell us is nowhere common or abundant. It is here one of the most familiar and characteristic of the summer wild flowers, growing in many damp, shaded grounds, and more conspicuously on the margins of small streams, often in patches of considerable extent. Occasionally flowers of the brightest and purest purple—even more pleasing and scarcely less striking—may be seen growing among the scarlet, both forms being well worthy of cultivation.

White forms of Spreading Phlox (*P. divaricata*) and Greek Valerian (*Polemonium reptans*) have here repeatedly come under my observation; also a white variety of *Lobelia syphilitica*. I have also noted specimens of the Virginia Lungwort (*Mertensia Virginica*), with the unfolded flower entirely pink or lilac, the type being pink in the bud and blue in the full flower. I have often met with specimens of *Rudbeckia hirta*, with their rays blotched with brown at their base, forming a distinct ring about the cone, adding much to the beauty of the flowers. These examples serve further to illustrate that

there are varieties or forms, as yet but little known, of many of our most familiar flowers, which possess, in a practical and æsthetic point of view, all the interest and value of an entirely new species, and which are well worthy of the attention of lovers and cultivators of wild flowers.

Fairview, Hancock Co., W. Va.

W. E. Hill.

A Chart of Standard Colors.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. C. R. Orcutt (vol. ii., page 622) points out a want very much felt by every one having to describe flower colors. It is, however, a fact that, owing to a difference in the construction of the eye, certain colors have a different appearance to one or the other observer. It would be a great advantage to science in general to have such a standard chart. If it be undertaken, it ought to be compiled by a commission of scientific men, including some good authorities. The large work of the French chemist, Chevreuil, might form the basis to work upon. A few years ago there was also a very exhaustive article in the *Gardeners' Chronicle*, which would be valuable in that matter. It apparently came from a competent authority.

Baden-Baden.

Max Leichtlin.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. C. R. Orcutt pleads (vol. ii., page 622) for a chart of standard colors. Such a chart is certainly a desideratum to all naturalists. But the difficulties in the way of its preparation and publication are very great, and I do not look for such a chart in many years, if ever.

In my own practice I use for this purpose an agent's sample-case of spool silks. The Brainerd & Armstrong Company, of New York, make a very neat and compact pocket sample-case which contains 220 named colors. This affords the best means which I have found of securing uniformity in observation and nomenclature between myself and assistants; and, in fact, it leaves little to be desired.

Ithaca, N. Y.

L. H. Bailey.

Easter Flowers.

To the Editor of GARDEN AND FOREST:

Sir.—The most beautiful display of Easter flowers made by any New York florist this year filled the windows of a large shop on Broadway between 27th and 28th Streets. On Thursday the principal window showed a line of potted Hyacinths, chiefly pink and lilac, set in a mass of Ferns. Behind these stood, in the centre, a large crimson Azalea with a Cytisus on either side, and beyond Roses, smaller plants of Cytisus and Lilies, all in baskets tied with ribbons of harmonizing colors. Back of this line were large Azaleas of paler pink varieties and a mass of Lilies and Bush Daisies, while lilac Cattleyas hung in baskets from the top of the window. The general effect was pink and white and green with dashes of yellow and lilac, and the window, as a whole, was both brilliant and harmonious. On Saturday the arrangement was somewhat changed; more white flowers, chiefly Lilies, being used with pink Hydrangeas, and more baskets of Orchids, some of them very beautifully grown and arranged. Inside the shop the most remarkable feature was *Lilium auratum*, in large numbers and excellently grown.

In other shop-windows less care had been paid to the arrangement of the plants. But I noted one place, temporarily hired by a florist of upper Sixth Avenue, where a very beautiful effect had been achieved in the interior. Rows of staging ran along the walls and down the centre of the long room, and supported, on the top shelves, files of large plants of Cytisus, making two little avenues of brilliant yellow, beneath which the other plants were grouped. There seemed few novelties among either potted plants or cut flowers. As was the case last year, many Orchids could be found; but the main reliance for plants was placed on Lilies, Hydrangeas, Spiræas, Cytisus, Bush Daisies and Azaleas, and for cut flowers, on Roses. The Hydrangeas were splendid, and the Azaleas, most often grown as standards with wide, round heads, had reached their highest point of perfection. Lilies were few and very inferior, and spring bulbs were not conspicuous, Daffodils being more plentiful than other sorts, but poor as contrasted with last year. The Lilies were fine, but universally marred by the loss of their anthers. Of course there is an excuse for this removal, but no one will deny that it greatly injures the beauty of the flowers, and to some persons it totally destroys their charm. Without the bright yellow sparks they seem flat, stale and unprofitable to the eye. There is no flower so much in demand as this for the adornment of churches. It is the accepted symbol of innocence and grace, and, moreover, has a peculiar consecration in

Catholic minds from its time-honored dedication to the Virgin. But to take off its anthers destroys its ecclesiastical signification for Catholics—though perhaps in this prosaic time and land they are not aware of the fact. They do not need to be told that the Lily is the Virgin's flower because "the pure white petals signify her spotless body and the golden anthers her soul sparkling with divine light"? However, if a Lily is purchased with some of its blossoms in bud, these at least will ultimately delight the possessor with both spotless petals and sparkling anthers.

New York florists complained that the damp, dark season had reduced their supply of flowers, but they must have done well with what they had from the empty look of their shops on Saturday night. Easter has, in fact, at least in this city, taken the place lately held by Christmas, and before that by New Year's Day, as the florist's busiest time. His trade then is largely with potted plants, of course; but gifts of cut flowers and even set pieces are now the rule, not the exception, and every parlor is abloom before the sun of Easter Sunday has set. Perhaps the profits of the Easter trade are not so great as those of the midwinter festival, but certainly its volume is getting to be surprisingly great.

New York.

Recent Publications.

The Horticulturists' Rule Book. By L. H. Bailey. New York Garden Publishing Company.

This little compendium embraces in its 200 pages much information which a gardener needs in his daily practice, together with some statistics and miscellaneous matter, which are interesting enough but foreign to the purpose of a handbook of this character. The best part of the work will be found in the first four chapters, which treat of insects injurious to plants and plant diseases, with the approved remedies for each. In no department of horticulture has the advance in knowledge been so rapid as it has been in this particular field during recent years. Discoveries have followed each other in such quick succession that the fruit-grower or gardener who reads the current literature of his art is quite bewildered by the variety of treatment recommended to prevent or cure the injuries from insects and fungi. The sufferers from these enemies have reason to thank Professor Bailey for having brought within the compass of fifty pages all the well established facts on these subjects that will prove of immediate practical service to them. This digest of the results of so much study and experiment is well arranged and indexed so that any one of ordinary intelligence can inform himself as to the character and composition of all the most deadly insecticides and the safest and most effective way of applying them. And the same is true of the remedies and preventives of fungous diseases. In no other work with which we are acquainted can there be found so much information on these subjects, in a compact and accessible form, and embodying the most recent experience.

While this is the best feature of the book, there are many other collections of tables, rules, recipes and directions for practice which help to make it a singularly useful manual for convenient reference.

Recent Plant Portraits.

Botanical Magazine, March:

ZAMIA WALLISII, t. 7103; a short-stemmed or nearly aculeous species from Guatemala.

SATYRIUM MEMBRANACEUM, t. 7104; a beautiful terrestrial Orchid, with bright carmine flowers, deepening to crimson on the back of the lip, from the neighborhood of Port Elizabeth, in South Africa.

ARISEMA WRAYI, t. 7104; a native of the Malay Peninsula.

LATHRÆA CLANDESTINA, t. 7106; a beautiful parasite of southern Europe, now successfully cultivated at Kew, where, planted on the roots of a Willow, it has increased, and flowered profusely.

PAPAVER RUPIFRAGUM, var. ATLANTICUM, t. 7107; a native of the Great Atlas south of the City of Morocco, where it grows at an elevation of from 6,000 to 7,000 feet.

ALLIUM KANSUENSE, *Gartenflora*, March 1st.

ALLIUM CYANEUM, *Gartenflora*, March 1st.

BILBERGIA × PERRINGIANA (B. nutans × Liboniana), *Gartenflora*, March 15th.

EUPATORIUM PROBUM, *Gardeners' Chronicle*, March 15th; a soft-wooded greenhouse plant, a native of Chili, whence it was introduced into England several years ago by the late Mr. Wilson Saunders, although not previously described, as pointed out by Mr. N. E. Brown, who now gives characters for it.

Notes.

Our correspondent, Mr. Rolfe, the English authority on Orchids, has been appointed an assistant editor of *Lindenia*, the great *Iconographie des Orchidées*, now in course of publication in Belgium.

Part I. of the new volume of *Hooker's Icones Plantarum* (vol. xx.) is devoted to different plants, principally Stapelias belonging to *Asclepiadaceæ*, the descriptions being furnished by Mr. N. E. Brown, of the Kew Herbarium.

A great "flower festival," similar to the one which was so successful last year, is being organized in Detroit by the *Journal* of that city, and will open on the 22d of April. The proceeds will be divided between a number of local charities.

The Manchester *Guardian* states that Dr. Jones, of Acton Hall, has discovered a chemical process by which the juice of apples and grapes can be manufactured into an agreeable non-alcoholic beverage which will keep for a number of years without fermentation.

A bundle of California-grown Licorice-roots was lately sent to the office of the *Tulare Register*. The editor of that paper asserts that the roots have the genuine licorice flavor and sweetness and cannot be distinguished from the imported article, and that the plant grows like a weed.

Premiums to the amount of \$250 were offered by John Gardiner & Co., for the best collection of spring flowering bulbs to be competed for at the Exhibition of the Pennsylvania Horticultural Society. The first prize was won by William Jamison, and the second by J. W. Colflesh. A box of Crocuses shown by W. K. Harris received special mention.

Prunus Davidiana, and its variety with white flowers, attracted much attention from visitors to the *Jardin des Plantes* in early March, as did a fine specimen of *Parrotia Persica*, covered with blossoms. This tree, still little known outside of botanical gardens, belongs to the Hamamelis family. It is especially ornamental by reason of its foliage, which does not appear till later in the season. Its flowers, of which the most conspicuous parts are the brownish red stamens, have little value.

L'Orchidophile remarks upon the flowering in the collection of M. Finet, in Argenteuil, of a *Lalia pumila* with white flowers, a variety not previously described; while another journal, the *Lyon Horticole*, mentions the exhibition at a meeting of the *Association Horticole Lyonnaise* of a giant variety of *Lycaste Skinneri*. It is called by its owner, M. Comte, *L. Skinneri grandiflora*, and is said to be remarkable for the extraordinary size attained by its leaves and flowers, which surpass anything hitherto recorded of this very variable Orchid.

According to the *Manufacturers' Record* 542,145 gallons of so-called Olive-oil were sent from Italy to this country during the year which ended June 30th, 1889, but its purity may be estimated from the fact that, within the same period, we sent to Italy 65,250 gallons of Cotton-seed-oil. Since that time our exports of this product have greatly diminished, possibly because, since the discovery of a test for the purity of Olive-oil, the Italian authorities have been able to control somewhat its manufacture. This discovery was made not long ago by the celebrated chemist, Becchi, and his test is said to be entirely reliable.

From an instructive bulletin lately issued by Professor Whitcher, of the New Hampshire Experiment Station, it appears that the commercial fertilizers sold in that state do not contain enough potash for the requirements of the soil there. It also appears that home-mixed chemicals can take the place of barnyard-manure as a source of plant-food. For the state in question a fertilizer should contain from nine to eleven per cent. of phosphoric acid, from nine to fifteen per cent. of potash, and from two to four per cent. of nitrogen. The prepared fertilizers in the market average eleven per cent. of phosphoric acid, two and a half per cent. of potash, and two and a half per cent. of nitrogen.

The term "gun fences," used by Mr. A. D. Mellick, Jr., in his recently published book, "The Story of an Old Farm," has, doubtless, puzzled many of his readers. Replying to a question put by one of them in the *Evening Post*, he says that gun fences, as formerly used in New Jersey, were "constructed of rails, often formed of lopped tree-branches, resting one end on the ground and the other in the air at an angle of about forty-five degrees, each one being supported a little above the centre by small cross stakes shoved into the ground. They were popular with the early settlers, because of their being so

easily and rapidly built, owing to their needing neither post-holes nor hewn posts. At a distance the rails did not look unlike a lot of guns stacked in line, hence the name."

The second part of Mr. H. Nehrling's "North American Birds" has appeared. It contains the completion of the account of the Mocking Bird, and descriptions of the Cat-bird, the Brown Thrasher, the Long-billed Thrasher, the Curve-billed Thrasher, the Crested Thrasher, the American Dipper, the Bluebirds, and the beginning of the Gnat-catchers and Warblers (*Sylviidæ*). The work will be finished in twelve parts, illustrated by thirty-six colored plates from drawings by Ridgway, Goering and Muetzel. It is published by George Bramder, 286 West Water Street, Milwaukee. The first part has received the highest praise from naturalists competent to judge of its value, and its excellence is fully sustained in the number before us.

The first number of *Le Journal des Orchidées*, a bi-monthly devoted to the cultivation of Orchids, has reached us. This new journal, the editor, M. Lucien Linden (Secretary of the *Orchidéenne*, and editor of *Lindenia*, etc.), tells us, has no scientific pretensions, and no other ambition than to be practically useful in giving as much information as possible upon the care and cultivation of Orchids. *Le Journal des Orchidées* is published at Brussels and will appear on the 1st and 15th of each month. It is a handsomely printed octavo of sixteen pages, without illustrations; and the first number, which contains a number of good articles, fully justifies the claim of the editor. The subscription price is ten francs a year, which may be sent to the office of the journal, 100 Rue Belliard, Brussels.

A western perfumer advertises the "phenomenal sale" of a new extract which he calls "Golden Rod perfume." If it has no more odor than the blossoms which, as he says, have won popularity as our "national flower," any sale, however small, must indeed be regarded as phenomenal; nor does it seem probable that the single species of *Solidago* (*S. odorata*), the leaves of which emit, when crushed, an anisette-like perfume, can be obtained in sufficient quantities for extensive distillation. There is frequent similar proof, however, that in this, as in other trades, it is difficult to supply a succession of "novelties" and fit them with attractive names without trusting a little to the credulity of the public. For example: if the Golden-rod is popular, the Orchid is "fashionable," and this is even better for advertising purposes. Therefore "Orchid perfumes" are now in the market bearing the names of several kinds, some of which have no fragrance whatever. Sometimes the makers are so discreet as to say no more in their advertisements than that they "reproduce" the odor of the given flower; but the name on the bottle seems like an attempt to make the confiding purchaser believe that he can inhale from it the actual breath of some rare, costly exotic.

American pomology has lost an ardent devotee in the death of Mr. Charles Gibb, which occurred in Cairo, Egypt, on the 8th of March. Mr. Gibb was born in Montreal in 1845, was graduated from Gill University at the age of twenty. On account of impaired health he sought out-door occupation, and after a visit to Europe he spent some time with prominent horticulturists in New York and New Jersey, an experience which strengthened his taste for fruit-culture and led to his adoption of that pursuit. Fortunately he was possessed of ample means, and on his return to Canada he purchased a large tract of land at Abbotsford, Quebec, where he established trial grounds for exotic trees and shrubs and planted extensive orchards especially of the more desirable Russian fruits. In 1882 Mr. Gibb visited Russia in company with Professor Budd, and the work which they accomplished in introducing Russian fruits to notice is well known. In June of last year he left Montreal for a journey through the East in the interest of fruit-culture and had visited Japan, China and India and was on his way home when death overtook him in Egypt. Mr. Gibb was a man of modest and retiring disposition, but his home at Abbotsford was the seat of wide and generous hospitality to all those who were interested in horticultural pursuits. He was singularly unselfish, and the horticultural and kindred societies of the Dominion, in all of which he took an active interest, bear witness to his public spirit. He prepared numerous papers which have been published during the last fifteen years in the reports of the Montreal Horticultural Society, the Ontario Fruit-Growers' Association, the American Pomological Society and similar organizations, most of which are of permanent value, especially those which relate to the fruit-trees of northern Europe, their nomenclature and their value for cultivation in the orchards of this continent.

Planting New Places.

THIS is the season when novices in planting, especially those who have recently acquired possession of suburban or country homes, are preparing to stock their grounds with ornamental trees and shrubs. The thought that thousands of new gardens are to be made would be a pleasant one, indeed, if there were any assurance that they would be well planned and planted; but the probabilities are that ninety-five out of every hundred of them will have no plan whatever, while the great majority of the trees and shrubs used in them will be selected without any adequate reason, and then badly planted in improper positions. This is a perfectly true statement and on its face it is discouraging enough. But the fact is that failure is the foundation of nearly all practical knowledge of gardening among amateurs, and the mistakes of this year will be an education for the next. When once a man or a woman either sets out in serious earnest to beautify the home-acre by planting trees and shrubs and flowering herbs, we may cherish a well-grounded hope that this is the beginning of an interest in gardening which will deepen with ensuing years and come to be at last an unfailing source of recreation and refreshment.

And yet if novices in the art of gardening would seek a little counsel at the outset and act upon it, their education would be much more rapid and much less expensive. They almost invariably begin at the wrong end, and gather their materials together first and then wander around their grounds in search of places to put them. The catalogues of the nurserymen offer to such persons a fascinating field of study. Naturally enough in these trade-lists plants of established merit are passed over with slight mention, for it is justly assumed that most buyers are informed as to their value. It is not surprising, therefore, that the novice, misled by the more circumstantial and perhaps a trifle over-colored description of the novelties and rarities and oddities among trees and shrubs, makes his selection largely from this class. The probabilities are that he will buy a great many more than are needed, and after he has

crowded them all into his place, he will begin to realize that it has no consistent purpose, no unity of expression, no meaning.

It is not probable that any marked success would have been achieved, but certainly the outcome would not have been so utterly unsatisfying, if a careful plan of the grounds had first been made. Let the amateur planter at the very outset make an accurate diagram of his grounds, drawn to a certain scale, so that he can note the space covered by any given tree or shrub. Next let him attempt to form in his mind a clear and definite picture of his future home-scene—such a picture as he will be able to construct with the verdurous material at his command—grass, shrubs, trees, flowers and festooning vines. No tree or shrub will then be selected merely because it is pretty, but because it fits in with the rest to give outward and visible expression to his thought. To accomplish this the mental picture will need to be distinct and vivid. It must embrace the relation of the house to the grounds. It should preserve and frame in any attractive prospects beyond the boundaries of the place, and shut out of view what is unsightly or incongruous. It must provide for walks and out-buildings and a hundred conveniences for the household in such a way that they will not disturb the harmony and fair proportions of his picture. When such a design is perfected it will not be difficult to make an order for the nursery, for it will be known exactly how many trees and shrubs are needed, and an intelligent reason can be given why each particular one was selected for its chosen position.

But is it probable that the beginner will be able to make a design which shall be so reasonable, consistent and complete? Perhaps not. But an honest attempt to make one, for which he can give an intelligent explanation, will be a pretty good way to convince him of the genuine difficulties of the situation. One part of an education consists in finding out how much there is to learn; and the novice may discover, before his design is finished, that it requires real artistic feeling and training to make a perfect cabinet-picture on a half acre of ground, as truly as it does to plan a park. He will realize that there are adaptations and adjustments to be settled in the very framework of his design and all through its essential elements which demand experience and thought. He will more than suspect that he has made a mistake in attempting to solve, off-hand and while the buds are bursting, problems of such puzzling complexity that an artist with years of practice behind him would hesitate to undertake them without ample time for study. He may divine at last that even a work of this magnitude may present an opportunity for displaying a comprehensiveness of treatment, a refinement and felicity of touch which will worthily exemplify the supremacy of the hand of genius.

One who has been educated up to this point will begin to look about him for a landscape-gardener of recognized attainment, and, more than that, he will be prepared to appreciate his counsel and to follow his instructions with confidence.

THE popular interest in Arbor Day is steadily increasing if it is measured with any accuracy by the growing volume of literature on the subject. We have just received the "Arbor Day Manual," which is a stout octavo of 450 pages, and handsomely illustrated. It has been prepared by Mr. Charles R. Skinner, Deputy Superintendent of Public Schools for the State of New York, and it contains selections in poetry and prose on subjects relating to forests, trees, shrubs and flowers, together with songs set to appropriate music, and its declared purpose is to aid teachers in arranging programmes for the celebration of the festival. This is the most elaborate treatise we have seen, but in some other states the manuals are nearly as large, while in many others a modest pamphlet prepared by some public officer is deemed sufficient. In Colorado, for example, the Forest Commissioner, Mr. Edgar T. Ensign, has issued a circular

which confines itself to some practical suggestions relating to the transplanting and culture of trees, and excellent suggestions they are. Mr. Ensign tells those who are interested in the day what kinds of trees should be chosen for the different portions of the state, how they should be arranged on school-grounds for the best effect, how the transplanting should be done and how the trees should be cared for afterward.

Of course, the sentimental side of the celebration has its uses, and the cultivation of an affection for trees and of an appreciation of their beauty is an object worth striving for. But the love for trees will be no less when it is associated with a knowledge of what they require for wholesome growth. Arbor Day will prove most beneficial in those places where the trees are not forgotten as soon as the songs have been sung and the poetry recited. If the memorial trees have been properly selected and planted, the teacher will help to encourage a genuine regard for them if he explains to the young persons in his charge why the ground about them should be kept free from grass, why it is beneficial to stir the surface occasionally or to mulch it well. If it appears on the next annual recurrence of this festival that the trees planted this year have been neglected, robbed of food and moisture by grass and weeds, loosened by the wind, preyed upon by borers or other insects, this will prove that the celebration has been a mockery, and all the feasting and oratory and music wasted on a sham.

Notes on North American Trees. XVI.—A Question of Nomenclature.

A WIDELY distributed *Xanthoxylum* of tropical America, with a geographical range from Florida to Peru, was described by Linnæus in the "Species Plantarum," published in 1753, as *Schinus Fagara*. A few years later he recognized the fact that his genus *Schinus* could not contain this plant, which he named in the "Amœnitates" (v. 393), published in 1760, *Fagara Pterota*. The next botanist to impose a name upon the plant was Patrick Browne, who called it *Pterota subspinoso*, in his "Natural History of Jamaica," published in 1789. Willdenow, in his enumeration of the plants cultivated in the Berlin garden, published in 1809, gave it a new name, *Fagara lentiscifolia*, citing a manuscript name of Humboldt and Bonpland. Finally, Kunth recognized that this plant might be referred to the Linnæan genus *Xanthoxylum*, and published in 1823 in the "Nova Genera and Species" of Humboldt, Bonpland and Kunth (vi. 3), *Xanthoxylum Pterota*; but in referring this plant to *Xanthoxylum*, Kunth passed by the earliest specific name, *Fagara*, which had also been used as the generic name of the plant by Linnæus and by Willdenow, and took up the later name, *Pterota*.

Under the principle that the earliest Linnæan specific name should, when not preoccupied, be adopted as the specific name of a plant, which I have followed in the "Silva of North America," this plant, which is one of the commonest of the small trees of south Florida, and widely distributed through western Texas, should be known as *Xanthoxylum Fagara*.

This name of *Fagara*, as applied to our plant, is due, too, to a misunderstanding. The name *Fagara*, according to Avicenna, the famous Arabian physician, was in use among the early Arabians to designate an aromatic plant of which the name is now lost. It was afterward taken up by Clusius and the early European apothecaries, who designated, under the name of *Fagaræ majores*, the aromatic fruit of some eastern tree which is supposed to be the *Xanthoxylum Rhetsa* DC of India. Linnæus, in his "Materia Medica," published in 1749, where he first mentions our plant, appears to have supposed that it was the origin of the *Fagaræ* of commerce, and so used later, in the "Species Plantarum," the old Arabian *Fagara* as its specific name.

The Art of Gardening—An Historical Sketch.

XIX.—The Arabs in Spain.

IN no land did the Arabs (or the Moors, as we more often call them in this connection) rise to so great a height of wealth, cultivation and luxury as in Spain. "No nation," says Draper,* "has ever excelled the Spanish Arabs in the beauty and costliness of their pleasure-gardens. Retaining the love of their ancestors for the cooling effect of water in a hot climate, they spared no pains in the superfluity of fountains, hydraulic works and artificial lakes. . . . There were also menageries of foreign animals and aviaries of rare birds. . . . Among flowering shrubs there were winding walks, seats cut out of the rock, and crypt-like grottoes hewn in the living stone. . . . Not only did the artist try to please the eye. . . . He also boasted of success in the gratification of the sense of smell by the studied succession of perfumes from beds of flowers." A recent writer,† speaking of the southern part of the peninsula, says that its gardens are survivals of the Moorish ideal of what a garden should be, modified by the requirements of country and climate. This ideal, in the hot, arid lands of the Arab's nativity, meant as much shade and coolness and moisture as could be obtained—thick bowers and vistas of foliage, plashing fountains, trickling rills and "creeping Roses and Jasmine to beget the perfume that his soul loves." In Spain so much shade was not needed and the gardens were made more open, yet shadowy foliage greatly predominated over sunlit spaces. Even in the days of the Renaissance, after the Moors had been expelled, many garden arrangements were but repetitions of their own, as, for instance, the very elaborate arabesques in oriental patterns which appear on a magnificent scale in the gardens of the Escorial, wrought with low clipped hedges of Box. "Another survival of Moorish times is the wall running by the garden-paths, hand-high, faced with painted tiles (*azulejos*), along whose top is scooped a deep furrow filled with garden-earth, and planted mostly with Carnations, Pinks and Gilliflowers, or the dwarf, sweet-scented Iris of Portugal. All these plants love the drought; and so set their flowers can be plucked or smelled without bending the back—an ingenious device of the ease-loving Oriental." Clipped hedges were frequently used by the Moors; but we read of no fantastically artificial shapes such as those that were beloved in ancient Rome and throughout Europe in the seventeenth century.

Every Moorish house had its court-yard, the original of the *patio* which is ubiquitous to-day in Spain. It was floored with stone or mosaics, openings being left for planting a few large trees. Smaller trees and shrubs stood about in pots with bright flowers growing around their roots. The walls were formed of simple loggias or fantastically rich arcades, according to the wealth of the proprietor, and arbors were constructed with vines upon a net-work of wire. A running spring occupied the centre, or, if water-power was available, a fountain took the place of the spring, and little holes were pierced in the pavement through which rose miniature jets. If a garden was connected with the house, it was regularly disposed with a multitude of canals and basins, broad, shadowy roads, and narrower paths overarched with flowers, trained on colored or gilded wire, leading to more open spaces where pattern-beds were planted with bright-hued flowers or arabesqued in Box. *Patios* were attached to the mosques as well as the houses, and an old Moorish example may still be seen near the cathedral of Seville.

The Moorish palace-garden was sometimes wholly formal in arrangement. The gardens of the Alcazar, near Seville, for instance, although greatly altered during Renaissance years, still preserve enough of their original character to be recognized as of Moorish origin, and they consist of numerous great square court-yards, divided from each other by walls and colonnades, like a succession of large *patios*.‡ But in other places we find royal gardens of a very different character, yet equally typical of Saracenic art—gardens which prove, indeed, that the charms of picturesqueness, mystery and variety were appreciated as well as those of balance and architectonic grandeur. The bold, varied character of the landscape in many parts of Spain, and its richness in contrasts between temperate and semi-tropical forms of vegetation, inspired the Spanish Arab to develop to the full that instinct for the wild, or seemingly wild, in gardening art, signs of which had already been displayed in Persia. Nothing could be less like the

* "Intellectual Development of Europe."

‡ Jaeger: "Gartenkunst und Gaerten."

formality of his *patios* and smaller gardens than the outer pleasure-grounds of the Alhambra and the Generalif near Granada.

Granada lies in a ravine cut by the River Darro, and extends out into the plain at the foot of the Sierra Nevada. The Alhambra rears its rosy towers from one of the mountain spurs, and the road that approaches it winds up from the city gate by a steep picturesque ascent to the main gateway of the palace. Théophile Gautier* describes this road as cut through a lofty forest and bordered by rivulets curling close to the roots of the trees, while from every crevice in natural rock or artificial wall gushes a bubbling spring; and a more recent writer† speaks in similar words of the constant yet irregular way in which water is everywhere introduced—tiny water-falls shoot out unexpectedly from the sides of the cliff, “suddenly to disappear into a yawning underground conduit. All this work,” he adds, “is entirely artificial, but is so completely in accord with its surroundings, so thoroughly artistic in thought, that it possesses the unstudied charm of nature’s best examples. Altogether, the outer gardens of the Alhambra are as delightfully planned as entrances to a realm of fairy-land as could be imagined. The Moorish landscape-work and the picturesque mysteries of the palace are revealed little by little. There is no general vista, no all-embracing view, but the imagination is left to picture what is dimly revealed through the fountains and across the fountains and under the wide arches, while, as in all Moorish work, the attention is held by half-disclosed attractions. This is the keynote of the whole arrangement—to awaken interest by unexpected surprises and half-concealed vistas.” Naturally, the aspect of this approach to the Alhambra must be much wilder to-day than when it was laid out in the thirteenth century. Yet the landscape-gardener builds, not for the hour, but for futurity; and the fact that his conception has here retained its charm while the passage of centuries has accented his first idea, is proof of consummate skill in the “art which conceals art.”

From this picturesque approach the Alhambra enclosure is entered through a great gateway, in the thickness of which the path makes two sharp turns, emerging as a steep roadway flanked by high walls that conceal everything but the “Vermilion Towers” of the palace at the top. It ends on a broad, flat, open terrace (once very extensive, but now partly covered by a huge Renaissance palace built by Charles V.), which affords a magnificent view over the ravine below and the course of the Darro. The original design of the gardens which spread before the palace cannot be deciphered, but, says Mr. Blackall, “the large terrace, with quiet, shady avenues leading from it, was probably then, as now, the central feature of the scheme.” The palace itself is so largely composed of a multitude of *patios*, filled with fountains and water-works of every kind, that, in Gautier’s words, it seems, “like many other Moorish habitations, merely a big, decorated fountain.”

M. G. Van Rensselaer.

Plant Notes.

Two American Honeysuckles.

THERE has always been a great deal of confusion in gardens with regard to the identity of two climbing Honeysuckles of the Eastern States which are sometimes cultivated—*Lonicera flava* and *Lonicera Sullivanii*; and it is only in recent years that botanists have comprehended the differences which distinguish these plants and their geographical distribution. The figures, therefore, of the two species, which appear on pages 190 and 191 of this issue, will serve, perhaps, to facilitate their identification.

Lonicera flava is an old inhabitant of gardens. The earliest mention of this plant was published in 1802 in Drayton’s “Views of South Carolina,” where it was described as growing on Paris Mountain, a low, isolated elevation near Greenville, in that state. John Fraser, a Scotch botanical traveler and collector, visited this place afterward and sent or carried plants to England in 1810. No other botanist, so far as is known, has ever been on Paris Mountain, and *Lonicera flava*, although it has been reported as growing in upper Georgia, is only known now by the descendants of Fraser’s plants, which have been kept in gardens, where, however, they are too rarely seen and are too little known;

while wild specimens are one of the chief desiderata in herbaria of American plants.

Lonicera flava (Fig. 33) has twining stems growing to a height of ten or twelve feet, broadly oval leaves, the two or three upper pairs connate into a broad disk, and, like the stems, quite glabrous. The flowers, produced in short, simple, terminal clusters, open here in June. The corolla is bright orange-yellow, the slender tube longer than the limb and hirsute-pubescent on the upper part of the interior. The filaments and style are glabrous. The bright scarlet fruit is ovate and contracted at the apex into a short point.

Lonicera Sullivanii (Fig. 34) was first noticed more than fifty years ago by Mr. W. S. Sullivan, who found it in Ohio, and who suggested doubtfully in his “Catalogue of the Plants of Columbus” that it was an undescribed plant. It was confounded, however, with *Lonicera flava* as a variety in Torrey and Gray’s “Flora of North America,” and in all the editions of Gray’s “Manual” except the last. Mr. Sullivan at the time of his discovery sent plants to the botanic garden of Harvard College, where it was propagated and quite generally distributed, but always under the name of *Lonicera flava*, and it is still almost always mistaken for that plant, which is extremely rare in gardens, being found now, so far as I have noticed, only in the garden of the Paris Museum and at Cambridge and in the Arboretum here; while *Lonicera Sullivanii* is not a rare plant in cultivation in eastern New England, where its large glaucous foliage is a familiar object in many country gardens.

Lonicera Sullivanii has feebly twining or sarmentose stems, rarely more than four or five feet long; and oval and obovate-oblong, thick, leathery leaves; those on the flowering stems are sessile and generally connate, the uppermost forming an orbicular disk. They become whitened, as do the stems, late in the season with a glaucous bloom, which makes this plant conspicuous and its recognition easy. The flowers are borne in elongated, loose, whorled clusters, often with a cluster in the axils of the second pair of leaves, and appear here at the same time as those of *L. flava*; they may be distinguished from the flowers of that species by their shorter corolla-tube, which is distinctly swollen or gibbous near the base, a little longer than the limb, pale yellow, marked with purple on the side exposed to the light. It is glabrous on the outer surface, and the filaments are glabrous or nearly so. The fruit is rather larger than that of *L. flava* and is nearly globular.

Lonicera Sullivanii is rather a widely distributed species, being found from central Ohio to Illinois, Wisconsin and the shores of Lake Winnipeg, and southward to central Tennessee. It has probably not extended much outside of New England as a cultivated plant; and if it exists in European gardens at all, it will probably be found under the name of *L. flava*.

These two species are handsome garden plants, especially *L. flava*. They are perfectly hardy and well worth cultivating, although their flowers are less fragrant than those of the English Woodbine (*L. Caprifolium*) or than those of the Japanese Honeysuckle. C. S. S.

Foreign Correspondence.

London Letter.

SOME plants of exceptional interest were exhibited at the meeting of the London Horticultural Society held at Westminster on March 25th. The Orchids call for attention first. A hybrid raised from *Cattleya Mossiae* and *Lalia cinnabarina* was an object of special interest, both to botanists and horticulturists. It was labeled *Lalia-Cattleya hippolyta*. It has a slender pseudo-bulb four inches long, a leaf six inches long by one and a quarter inches in breadth, and a flower five inches in diameter, spreading as in *L. cinnabarina*, the sepals half an inch and the petals an inch wide, the labellum two inches long, narrow, tubular, crisped and wavy in front. Its color is a uniform tawny yellow of a pleasing shade. It was

* “Voyage en Espagne.”

† C. H. Blackhall, GARDEN AND FOREST, I., 255.

exhibited by Messrs. James Veitch & Sons, who raised it. The only other hybrid raised in gardens, and of which *L. cinabarinum* is one of the parents, is *L. flammea*, a plant of somewhat similar character to the new one. *Dendrobium Wardianum*, Schroeder's variety, was remarkable for its large flowers and their deep color, the sepals being wholly rich amethyst, with a margin of white; the petals white, tipped with amethyst, as also was the lip. *Cattleya Trianae Schroederi alba* is a white flowered fragrant variety of exquisite form and large in size; the lip is blotched with pale yellow. *Odontoglossum Leeanum* was represented by a large specimen bearing a stout, many-flowered spike. This is one of the best of the many forms of *O. odoratum*, its flowers being unusually large, bright and clear in colors, and prettily marked on the lip. *O. Sanderianum*, *O. Hebraicum* and *O. gloriosum* are its near allies. *Dendrobium nobile nobilius* was in its best form, a most gorgeous flower, with petals an inch broad and colored the richest glowing amethyst. Many plants which are called by this name have small claim to it. *Phajus Cooksoni* was again shown, its flowers this time showing a distinct yellow color on the under portion of the lip. *Angracum sesquipedale* was shown with gigantic flowers fully nine inches across the segments, the spur measuring thirteen inches in length. *A. citratum giganteum*, a most elegant plant, bearing four spikes, each fifteen inches long, and the individual flowers an inch in diameter, or almost twice as large as the type. This is one of the most charming of the *Angracums*. *Calogyne Cummingsii* is a rare species seldom seen in flower; it has erect scapes with medium sized white flowers, the deeply fringed crest colored yellow and brown. *C. pandurata*, the giant of the genus and a most remarkable Orchid in respect of color. Its flowers, which are fragrant, measure four inches across, and are borne about a dozen together on a stout, erect spike (Lindley says pendent), are colored pale pea-green, except the lip, which is yellowish green, warted and marked with large irregular blotches and veins of ink-like black. *Cyrtopodium Legerianum* was represented by two huge specimens bearing immense spikes, or rather sheaves, of yellow and brown flowers. Mr. Cummings, who grew these specimens, informed me that he has flowered them now three years in succession by growing them in pots partly submerged in a water-tank and feeding them liberally with Clay's manure all summer. During the winter they are placed in a vinery and kept dry. A wonderful example of *Oncidium sarcodes* bearing two spikes about eight feet long with many branches and crowded with flowers, revealed capabilities in this species not previously suspected. Spikes two feet in length have been considered good for this *Oncidium*.

Other noteworthy exhibits were *Epiphyllum Gartneri*, a beautiful and distinct Cactus of great promise as a garden plant. *Hamantus multiflorus*, a tropical African species and one of the best of the genus as a stove-flowering plant; its scape, which precedes the leaves, is a foot high, and bears a globose head, nine inches through, of rich crimson flowers, which remain fresh a fortnight or more.

Cannell showed stands of his marvelous Pelargoniums and double Cinerarias. B. S. Williams sent a collection of *Clivias* of the best kinds. By the way, the writer of the note in GARDEN AND FOREST on *Clivias* was in error in stating that many hybrids had been raised from the species of this genus. As a matter of fact, there is only one hybrid, *C. cyrtanthiflora*, raised by Van Houtte about fifteen years ago from *C. miniata* and *C. nobilis*. The many named garden forms of *Clivia* are all seedling sports of *C. miniata*. A new and enlarged form of Lily-of-the-Valley was shown, its spikes a foot in length, and crowded with bells of large, well shaped flowers, the leaves also being unusually large.

Kew.

W. Watson.

The Veitchian Nurseries.

CHELSEA, a suburb of London bordering the Thames on the Middlesex side, has always possessed famous gardens. The Botanic Garden of the Apothecaries' Society was founded here more than two hundred years ago, and for about a century and a half occupied as prominent a position in botany and horticulture as Kew does now. Ranelagh and Cremorne, the two favorite pleasure resorts of the wealthy of the last century, flourished here, Chelsea then being "a pretty village, two miles from London." It is very different now. The Botanic, or "Physic," garden remains, a withered cripple of its former self; the builder has long since taken possession of Ranelagh and Cremorne, and instead of being a pretty village, Chelsea is an enormous workshop, with a population considerably over a quarter of a million. Its famous gardens of the present time are nurseries, and the most famous, not

only here but in the whole world, is the Royal Exotic Nursery of Messrs. James Veitch & Sons. Some account of an establishment which for over half a century has exercised a very great influence on the development of English horticulture, and has a staff of over 400 employees, will probably interest American readers.

It is customary to speak of the nurseryman as a mere tradesman, whose sole object is to make money out of horticulture. This may be true of the majority, but there are and always have been in England nurserymen who have taken a leading part in all movements for the advancement of horticulture from pure love of the work. By forming magnificent collections of plants of all kinds, both ornamental and useful, and by showing that they may be successfully and easily grown in a garden, these nurserymen have contributed more, perhaps, than any other body of men or institution to foster a love of horticulture among the people of this country. The names of Switzer, Lee, Abercrombie, Loddiges, Backhouse, Rivers and Veitch will always be placed amongst those to whom horticulture owes most.

The Royal Exotic Nursery, Chelsea, was established in 1814 by Knight & Perry. From its commencement it has held a foremost rank amongst the nurseries devoted to the introduction and cultivation of new plants. In 1853 an advertisement in the *Gardeners' Chronicle* announced that this nursery had become the property of James Veitch & Sons, of Exeter. The nursery at Exeter was conducted by the father and grandfather of James Veitch, and it had been for many years one of the principal nurseries in England in the days when Loddiges, at Hackney, and Rollison, at Tooting, were in full swing. The young James Veitch was apprenticed to Rollison, with whom he acquired that taste for and love of exotic plants, and especially of Orchids, which was of so much service to him at Chelsea.

It appears that the grandson was the sole owner of the newly acquired Chelsea nursery, the partnership with his father being only in regard to new plants which they conjointly introduced and shared. Collectors were despatched to America and the East, amongst them being the brothers Lobb, Pearce, Hutton, and Mr. Veitch's son, John Gould, who went to Japan and the South Pacific. The many beautiful and interesting plants that were thus obtained enriched horticulture as it had never been enriched before, with all kinds of conifers, including the Sequoia, Acers, Orchids, Nepenthes, Begonias, Liliiums, *Berberis Darwinii* and others.

In 1869 James Veitch died, the connection with Exeter was severed, and the management of the business devolved on the three sons, Harry J., John Gould and Arthur. The father was a man of remarkable energy, clear-headed, a most skillful cultivator and a true son of Adam. It was said of him that "a quick temper and impatience of opposition were natural adjuncts to a character such as his; but at the same time there was thorough conscientiousness and straightforwardness, a disgust for all semblance even of meanness or underhandedness." In the following year John Gould died at the age of thirty-one, and in 1880 Arthur also died, leaving the business to be managed by Mr. H. J. Veitch. Two of his nephews have lately joined him in the management. The development of the nursery and the amount of important work done in connection with it during the last ten years have been most remarkable. In the introduction of new plants; in cross-breeding Orchids, Rhododendrons, Begonias, Hippeastrums, hardy flowers and vegetables and in the superior cultivation of almost every class of plant, Messrs. Veitch occupy the premier position among English nurserymen. Besides all this, the publication of their most useful "Manual of Coniferæ" in 1881, of the classical and scientific "Orchid Manual" now in course of publication; the numerous papers prepared for the Linnæan and Royal Horticultural Societies, are evidences of a zeal in the cause of horticulture, a desire to help forward the science and the art, of more than an ordinary kind. Messrs. Veitch may be "making a fat thing" of their nursery work, but they are also doing a great deal more than most people to make gardening easy and delightful as well as remunerative.

The Chelsea nursery is only five and a half acres in extent, but it is almost wholly covered by 110 glass houses, many of them large. The entrance is through a long, lofty glass corridor banked with Ferns, Palms and other foliage plants, the whole of the roof being covered with red and white Lapagerias. On the right is the suite of offices, where a staff of twenty clerks is employed. On the left of the corridor are the large seed and bulb warehouses, an enormous business being done in this department. The corridor is terminated by a high house in which a collection of Tree Ferns, Cycads and large Palms are kept. From this the visitor may turn to the left and walk

through house after house filled with *Araucaria excelsa* (here first propagated with success by the late Mr. Court, one of the cleverest propagators we have ever had), Ferns of every sort, large Todeas and other filmy fronded kinds; big and little Adeantums, Davallias, Aspleniums, and in smaller houses all sorts of secrets in the shape of new kinds, which one may look at but not write about. Then we pass into a house or rather a pretty rockery covered with Ferns and protected by a glass roof. This house, delightful as a grotto in summer, is a kind of anteroom to the Orchid-houses. There are twenty-five of these, every one crammed full of plants, big specimens, pigmies, rare hybrids, new introductions, popular favorites, all elbowing each other and fat with health and happiness. Two houses filled with specimen *Cypripediums*, another with *Vandas* and *Aerides*, another with *Phalaenopses* and so on. The *Odontoglossums* make a brave show just now and amongst them are many gems of the cool house; *Sophranites* forming brilliant patches of scarlet; *Odontoglossum Humeanum*, *O. Edwardii*, *O. nebulosum* and *Oncidium Phalaenopsis* being conspicuous among the rest. The *Cattleya*-house, 132 feet long, twenty-two feet wide and fourteen feet high, contains thousands upon thousands of plants, some large specimens a yard across, others quite small, but all full of plump flower-sheaths of great promise for the blaze they always make in May and June. There are sixteen rows of four-inch pipes in this house, which is heated by an eight-foot *Trentham* boiler. Two broad lean-to houses have their roofs swarming with all sorts of *Dendrobiums* in baskets; and now we are in the show house for Orchids. It is about thirty feet square and twelve feet high, without any staging, the sides being built up of cork and stone and the middle occupied by a large irregular mass of the same material surrounding a cascade and tank. Pockets are cunningly made for the reception of the pots containing the plants, the cork and stone is more or less clothed with creeping *Ficus*, *Selaginella* and similar plants. The effect is particularly natural in appearance and pleasing. At the time of my visit the plants in flower in this house were *Epidendrums* of various kinds: *Calogyne Massangeana*, *Cymbidium Lowianum* and *C. Devonianum*, a white *Lycaste* with gigantic flowers seven inches across; *L. fulvescens*, with forty of its large, tawny, yellow flowers; *Phajus tuberosus*, *Dendrobium Cambridgeanum*, *D. Wardianum*, *D. Farmeri*, the white *Calogyne cristata* and many others. The *Nepenthes*-house is fifty feet long and contains a magnificent display of pitchers, Messrs. Veitch having been exceptionally successful in the cultivation of these plants from the first. *N. Rajah*, *N. Dicksoniana*, *N. Mastersii*, *N. Morganii* were in glorious form. Then we enter a house filled with *Anthurium Scherzerianum*, grand examples of good cultivation. A similar house is filled with *Clivias* in flower. The specimen greenhouse *Rhododendrons* fill three houses, whilst in smaller and propagating houses there are hundreds of thousands of these plants, from the tiny seedlings just hatched to the latest flowered of the new hybrids. The first hybrids were raised at Exeter some thirty-five years ago, but the best of those now known have been obtained since 1877.

In the houses devoted to new plants there are numerous new introductions from all parts of the world undergoing operations by Mr. Heale, the clever propagator and hybridizer, but of these I must not now write. *Lapageria alba* has a house to itself. Numerous specimens are planted in a peat bed twenty-five by ten feet. The shoots of this are led by strings up to the roof. These when ripe will be laid flat on the soil and covered with an inch or so of sandy peat. The result will be that hundreds of shoots will be pushed up, and these when rooted will be lifted and potted separately. By this ingenious method of layering an abundant stock of this popular greenhouse climber is obtained.

Another propagating house is filled with seedlings of all kinds: *Clivias*, *Streptocarpus*, *Begonias*, *Cacti*, *Rhododendrons*, including those wonderful Yunnan species, the introduction of which, unless report and dried specimens speak falsely, is an event of more than ordinary importance.

Hippeastrums fill a house sixty-five by eighteen feet, and the two thousand spikes they now bear present a wondrous array of brilliant colors and huge flowers. The popularity of these plants is shown by the enormous number sold from this nursery alone, which is something like two thousand every year. A hundred of Messrs. Veitch's seedling *Hippeastrums* have been certificated. Seedlings flower at the age of three years, and probably remain healthy till they are ten years old.

A pretty conservatory always filled with the flowers of the season is useful as a kind of sample-room. Parallel with it is a group of ten houses placed side by side; opposite to them,

on the other side of the central path, being a similar group. Ten of these long, low houses are filled with healthy young stock of hard wooded plants, such as *Boronias*, *Aphelaxis*, *Eriostemons*, *Ericas*, *Correas*, *Pimelias*, *Epacris*; Climbers of all kinds; young *Azaleas*, and so on. It is a long business to "do" the whole of these houses, interesting though the contents of every one undoubtedly are. The other ten of these useful structures contain stove plants of all kinds. A Palm-house crammed with large specimen *Kentias*, *Cocoses* and other decorative kinds; then follow three large houses of *Camellias*; another is filled with specimen *Aralias*; five others are devoted to the growing of pot-vines, of which Messrs. Veitch grow 4,500 every year, and even these do not supply the demand. A corridor leading to the high road contains magnificent specimens of *Camellia*, all in flower. The propagating houses teem with myriads of baby plants of every kind. New *Nepenthes* are here cared for and multiplied. Here, too, are young plants of the interesting *Heliamphora nutans*, cousin to the *Sarracenia*, and till lately shut up on the top of the *Roraima* Mountain.

About a dozen long houses contain soft-wooded plants, such as *Bouvardias*, *Pelargoniums*, *Fuchsias*, *Cyclamens*, *Carnations*, etc. Then there are frames innumerable, beds filled with *Carnations*, which grow well at Chelsea in spite of the poison of its fogs and smoke. The keep of this nursery is most admirable. "A place for everything and everything in its place" is the motto here.

I have omitted to mention the breeding houses for Orchids so ably presided over by Mr. Seden, because they, or rather their contents, have been taken to a branch nursery at Slough, near Windsor. Messrs. Veitch have also branch nurseries at Fulham, at Chiswick and at Coombe. These, however, can be dealt with in another letter. It is needless to say that Americans interested in horticulture are always welcomed at the Veitchian nurseries, where they can see as much perhaps in a short time of exotic garden-plants as anywhere in the world.

Some Adaptations in the Strawberry.

THE Rose family has shown remarkable power to keep pace with the human family, and its adaptability to our needs and moods is one of its peculiarities, especially in the case of the small-fruits. The Strawberry has of late done a good deal in the way of adjusting itself to cultivation. Two years ago I received some plants of the *Haverlands*, and was astounded to find the roots a foot long in some cases. One trouble with our Strawberry-beds has always been a tendency to heave out with frost. But it seems now very probable that we shall develop plants with such a strong hold on the soil that heaving will be rare. It occurred to me that these *Haverlands* had put all their energy to roots and would show poor fruiting power; but experiment proved that the contrary was true: the plants were very prolific bearers of very large berries of excellent quality. Since receiving the *Haverland* I have found that several more of the newer sorts are developing the same tendency to extraordinarily long roots: *Viola* and *Crawford* are two fair samples of root evolution. *Tippecanoe* is said to have extremely long and massy roots, but I have not yet tried it. Clearly, it is along the line of root improvement that selection should take place as well as along the line of fruit enlargement. But the development of large fruit is, of course, what catches the popular eye and meets the consumer's desire. Those of us who remember the introduction of the *Wilson* and *Hovey* have in mind a remarkable history. We have gone on from the field berry until now a well cultivated bed of *Sharpless*, *Bubach*, *Summit*, *Ontario*, *Haverland* or *Crawfords* will give us thirty to a quart. So far as size of fruit is concerned we have gone quite far enough. The point now is to eliminate the inferior sorts. New applicants for favor need not recommend themselves on the score of being larger than a half dozen of the leading sorts already disseminated.

The three points to consider hereafter are quality and form and color. *Crescent* is, perhaps, the ideal in color, but apart from its ability to produce bushels of sour berries, averaging small, it has no claim on us. The *Wilson* has slowly been discarded, as we discarded the old *Bouchretien* Pear. No sour berry or one of inferior flavor will hold its place with consumers. The public taste has been educated to the standard of the *Seckel* Pear. Form, also, must be considered, until we can dispense with *Sharpless* and other irregular and coxcomb sorts. *Cumberland* is an ideal in form, but lacks somewhat

in substance; it is not a good carrying berry. For quality we have nothing quite to equal Lennig's White, or to surpass Prince of Berries after that; but the first of these yields a very thin crop, and the second is not profitable as a cropper, nor has it sufficient foliage and stem. The Crawford comes as near as any that I have seen to cover all demands as to quality and form and color. I have not grown it, and cannot speak for its roots. Haverland is an ideal berry, except that it lacks the very highest flavor.

I do not anticipate any startling progress in the Strawberry hereafter. We shall probably collect into a few sorts the fine points now rather scattered among many, and then content ourselves with what has been accomplished. The last half century history of this plant and of fruit adaptation make a charming chapter in the general story of the relation and co-operation of the human family and the Rose family.

Clinton, N. Y.

E. P. Powell.

[Is it not probable that longer roots in new varieties have been developed by high culture in deeply worked soil?—Ed.]

they appear if the plant is to be used especially for the effect of its foliage.

Drymonia Turialvæ is a native of South America and is an easy subject to grow, its chief requirements being a warm shaded house and plenty of water, and almost any light, rich soil. It should be allowed ample pot-room, or the foliage will not attain its full size, though a good plant may be grown in an eight or ten-inch pot. It is propagated by cuttings, which may readily be procured by heading it back so as to induce the side-shoots to break, or the plant may be cut up into single eyes—either method being successful. In fact, the *Drymonias*, in common with many others of the *Gesneraceæ*, will root from leaves, though it may take a considerable time before the rooted leaf will form an eye at its base from which to send forth a shoot.

TAPEINOTES BICOLOR.—This is another interesting Gesneraceous plant which is also a native of some parts of South America, notably of Brazil. It is, perhaps, the best species of a small genus which is nearly related to *Nematanthus*, and it has small tubular white flowers, the tube being of peculiar

Fig. 33.—*Lonicera flava*.—See page 187.

Good Plants for the Greenhouse.

DRYMONIA TURIALVÆ.—Among the many handsome and interesting plants belonging to the *Gesneraceæ* this one deserves a prominent place, for, when well grown, it makes a very attractive specimen, and is of such dimensions that room can be made for it in small collections. This *Drymonia* is not a new plant, but it is so rarely seen that it would easily pass for a novelty in many establishments. It has opposite, ovate, heavily veined leaves from one foot to fifteen inches in length, and broad in proportion, with their upper surface of a peculiar silvery gray tint, while their under surface is a dull purplish red. The flowers are axillary, creamy white, tubular, with fimbriated edges, produced on short stems, and, while ornamental in themselves, are borne so freely as to interfere in a measure with the size of the foliage if allowed to remain on the plant. It is, therefore, best to pinch out the flowers as

shape and produced from the axils of the leaves. The leaves are rather glossy and olive-green in color, and the entire plant is more or less hairy. *Tapeinotes bicolor* is also very easily increased by cuttings, and requires similar treatment to that recommended for the *Drymonia* in regard to heat, shade and moisture. It is, however, much smaller than the preceding, and does not require so much pot-room in proportion to its size. It will also be found more satisfactory to grow either of the above mentioned plants from young stock each season, as they are of rapid growth and soon attain their best condition.

STREPTOCARPUS.—In the extensive family of *Gesneraceæ* are to be found many peculiar plants, and in the latter category may certainly be placed the genus under consideration. Probably the most prominent species of this odd genus is *Streptocarpus Saundersii*, which has the strange habit of producing but one leaf, which is dark green on the upper surface and

reddish beneath, somewhat tomentose, and a foot or more in length. From the base of this solitary leaf rise the flower-spikes, bearing large panicles of lavender-colored flowers, the individual flowers not being very large but showy in the mass. A smaller species than the above, and also very pretty, is *S. Rhexii*, which flowers in much the same manner and profusion as *S. Saundersii*, but produces a pair of leaves instead of the solitary one of the latter.

All the species of *Streptocarpus* are multiplied by seeds, and may be grown in an intermediate house, where the temperature is kept at about fifty degrees. They should be potted in light loam in well drained pots or pans, and if a number of plants are placed in a pan, so as to form a mass, they make an effective group and produce a succession of bloom for a considerable time. They enjoy a plentiful supply of water, but it should be so applied that the foliage is wet as little as possible, for the leaves are liable to damp off if watered overhead.

The *Streptocarpus* is native of South Africa, and although

winters. This is, also, unfortunately true of some of the best western species.

Pentstemons seem to thrive best in a light, rich soil, in the open border, and in such a position all are perennial. *P. grandiflorus* is one of the showiest we have grown. It has spikes of pretty bluish lilac flowers and grows about two feet high. It has glaucous foliage, seeds freely, and self-sown plants produce better flowers than old ones. There is a variety of *P. grandiflorus* with dark purple flowers which is distinct and desirable. It seems constant, having come true from seed, and bids fair to be a popular plant. *P. Cobaea* has, perhaps, larger flowers than the last, and these bear a striking resemblance to the old *Cobaea Scandens* of greenhouses, with its purple, white striped flowers. The variety of *P. Cobaea* known as *Purpurea* has much darker flowers and is quite distinct. This may also be easily raised from seed. *P. ovatus* is a species with pretty bright blue flowers, which change to purple, and though in this species the flowers are smaller than in those named above, they are much more abundant. This

Fig. 34.—*Lonicera Sullivanii*.—See page 187.

the above mentioned species have been in cultivation for many years, they are seldom seen in American collections. And yet they are more worthy of cultivation, both on account of their oddity and beauty, than many plants which are much more common.

Holmesburg, Pa.

W. H. Taplin.

Pentstemons for the Garden.

THE genus *Pentstemon* is an extensive, and, with one exception, a peculiarly North American one, many species being desirable plants for the hardy-flower border, while others are showy but not hardy here in the Eastern States, and others again are of botanical interest only. One of the great charms of the English flower border in the summer months is the beautiful race of florists' varieties of *Pentstemons*, and it is much to be regretted that these are not suitable for cultivation here, being too tender to withstand our

plant is best propagated by cuttings taken in fall and wintered in pots in a cold frame. *P. diffusus* is a species of dwarf branching habit and pretty blue flowers borne in great abundance. This plant is liable to be injured in severe winters, but does well with a little protection. *P. pruinatus* is a rare species also of branching habit and bright blue flowers on stems two feet high. These two last species are also best propagated from cuttings. *P. barbatus*, var., is one of *Torreyi*, the best known in gardens and deservedly so. Its tall panicles of brilliant scarlet flowers often grow five feet high, and last in bloom all through summer. It is easily propagated by division. *P. laevigatus*, var. *Digitalis*, is a good garden plant with showy spikes of white flowers which last a long time in bloom. This plant has a more eastern range than any of the preceding, and has a robust constitution. There are many other fine species of *Pentstemon* which would be desirable acquisitions to gardens if they would prove hardy, and of these may be mentioned *P. Hartwegi*, *P. Eatonii*, *P. centranthifolius*,

P. spectabilis and *P. puniceus*, the two last being among Dr. Thurber's discoveries. We should be glad to hear of living plants of these last.

E. O. Orpet.

The Spring Garden.

THE Chionodoxas, popularly known as "the Glory of the Snow," a free translation of the botanical name, are among the most valuable additions of recent years to the spring garden. As the name implies, the plants are supposed to bloom in the melting snows, and, in fact, follow closely the blooming of the Snowdrops.

C. Lucilia was introduced about a decade ago and immediately excited attention by its brightness and beauty, and has evidently taken a permanent place in gardens. As it has been widely distributed by the trade, this variety is probably now very well known by most fanciers of hardy flowers, though possibly many have yet to discover its beauty when grown in liberal breadths. Like many of the small spring flowering plants they should be planted in masses, and even then they require a year or two to produce a satisfactory effect. *C. Lucilia* is found in Asia Minor only, as far as known on the Nymph Dagli Range, near Smyrna; it is a free-growing variety with one or more scapes, furnished with from two to six erect flowers with narrow white petals, tipped bright blue of the clearest shade—altogether a beautiful addition to any border. The flowers are variable in size, but in good examples are over an inch in diameter. There will be found, also, a difference in the shades of blue in the tips. Sometimes, though rarely, pure white and rose sports are found. The former of these is a lovely pure flower, and would be a valuable plant in the border could stock be had. The rose-colored sports are tinted with blue, a color not entirely pleasing. My stock of these was grown in a pan in a cold frame, which may partly account for their not being with me, at least, as strong as the parent plants.

C. Sardensis was found a few years since on the Mahmoud Dagli Range in sight of the plain of Sardis. This flower has a small white eye and the deep blue of the outer color of *Scilla Siberica*. My colony came into bloom in February and seemed to be much affected by the bad weather, so that, possibly, the newly planted bulbs may not have done their best; but, so far as I can judge, the color effect of *S. Siberica* is superior in this shade to *C. Sardensis*.

C. gigantea is a later collection from the Tmolus Range, and a very distinct, pleasing flower. The color is rather on the light violet-blue shade, with lines of darker blue. My corms are small, and flowers, perhaps, not at their best in size; but I should rate it as next to *C. Lucilia* and worthy of a place among the best flowers. This variety was latest in blooming.

C. Tmolusi is the latest variety collected by Mr. Whittall, but which I have not yet seen. It is described as a magnified *C. Lucilia*, with a deeper tint on the petals. From the collector's description it is possible that this variety is too near *C. Lucilia*, which is rather variable in size and coloring, to be considered a distinct variety. It has been collected in a different station; but when the two are cultivated together it will probably be found that the resemblance is too close to entitle them to separate names, for garden purposes at least.

C. Cretensis was the earliest Chionodoxa to bloom; but its value does not seem very great, though the waving scapes, covered with the whitish flowers, are rather graceful, and appeared when flowers were rather scarce. J. W. Gerard.

Elizabeth, N. J.

THE Dwarf White Trillium (*Trillium nivale*) is a charming little plant when well established. It comes into bloom as early as the earliest, lasts for several days, and the honey-bees swarm about the beds where it is planted as soon as the weather is warm enough for them to fly. The average height of the plant is only about three inches. It bears a single white flower an inch or more across. The three leaves, which are borne in a whorl half an inch or more below the flower, are of a waxen green, with a purplish tinge, and add much to the value of the plant. This species is not a native of New England, but is common in some parts of Ohio, Illinois and Wisconsin. It needs a fine loamy soil, with a thin shade. It should be planted in early autumn or midsummer in order to become well established before winter.

A variety of the White Dog's-tooth Violet (*Erythronium albidum*, var. *coloratum*), from Texas, now in flower, is the earliest we have seen of this genus. It is perfectly hardy, a strong grower, and, after it is established, a free bloomer. The flowers are about the size of those of the typical species, but instead of being white are of a pinkish purple tinge, and very

pretty. It is a newly-discovered variety and well worth growing.

Chionodoxa Lucilia and *C. Sardensis* are in bloom, and on account of hardiness and earliness are very desirable. In order to do well, they, too, should be planted in early autumn or midsummer. It is better to plant these early-flowering kinds as soon as they have seeded, as they are sure to bloom earlier the following spring than if not set until October. We have noted this difference in beds of Trilliums of the same kind, when some were planted early and others later. Those which were set in midsummer were a week or more in advance of the later ones.

Insecticides for Window Plants.

IT frequently happens that, despite the greatest care, insects, more especially plant lice (Aphides), will find their way into window gardens and small conservatories, sometimes seriously marring the beauty of the plants, and even of the flowers. The insecticides and methods of application recommended for destroying these pests on a large scale are often not applicable to these small gardens, which yet frequently suffer much more seriously from insect attack than do outdoor plants. Caterpillars of larger lepidoptera rarely get at these plants, and where they do hand picking is the best remedy. The little leaf rollers are much more apt to be found, and, when observed, are also most easily disposed of by being crushed in their habitations. Beetles that visit the flowers rarely do any damage, and their larvæ, where they are plant feeders, are amenable to the same treatment adopted against plant lice. These latter, and sometimes the little jumping plant bugs, are the most usual pests on house and conservatory plants. They cluster on the leaves, often causing them to curl, to become dry, brown and unsightly; on stems, causing them to become hard and woody, and on flower-buds, causing them to become aborted or to produce crippled and imperfect flowers.

In my experience, Pyrethrum and Tobacco, properly used, have both been found very effective in ridding the plants of all insects infesting them. My preference is in all cases the dry powder, applied pure and with a bellows that will enable it to be put on rapidly and evenly. It is essential to the entire success of these substances that they be very finely ground, and in this respect I have found the Persian and Dalmatian powders much more satisfactory than the Buhach or California grown Pyrethrum. The Tobacco powder should also be very fine and very dry—as near a dust as it is possible to get. In this shape I have seen it in a very few minutes clear several large Rose-bushes of their enemies. Another, and perhaps more economical and about equally effective, way of using these substances is in the form of a decoction, using one ounce of Pyrethrum or Tobacco to a pint of water. Steep as in making tea and allow it to draw well. The Pyrethrum must be kept in a tight vessel, while the Tobacco infusion loses nothing by exposure. Apply with an atomizer, such as is obtainable in all drug stores, straining the liquid before putting into the bottle for application. Both substances are almost immediately effective—the fine spray reaching everywhere, and adhering to the insects where larger drops would be shed and ineffective. The Tobacco infusion could be prepared and an atomizer kept charged near at hand, so that at the first sign of insects it could be applied. In this way house plants and small conservatories can be easily kept free from insect injury of nearly all kinds.

Rutgers College.

John B. Smith.

Chrysanthemum maximum should be found in every hardy-plant border. It is a magnificent plant after midsummer, beautiful in the border, and valuable for cutting at the very hottest season of the year. *Pyrethrum uliginosum* so much resembles a Chrysanthemum that it may well be classed with the above. It flowers late in September and lasts three weeks or more. The plants are larger than those of *C. maximum*, and they "break" like garden Chrysanthemums, making bushes three or more feet high and of proportionate breadth literally covered with flowers in their season. These flowers are not so large as those of *C. maximum*, but they are considerably larger than Ox-eye Daisies or Marguerites, which they resemble in other respects. The Pyrethrum is perfectly hardy and thrives under ordinary treatment.

Pearl River, N. Y.

John Thorpe.

Seasonable Hints.—For successful gardening it is quite as essential to know what to avoid as to know what to do, and it is particularly important to know just when to do it. The careful cultivator keeps a diary of operations for each year with an

accurate account of what was done at every date and the general weather conditions at the time, and to this he adds as the season progresses notes relating to the success or failure of crops and the apparent reasons for both. Every one who has an interest in a garden should begin a diary of this sort if this has not already been his practice. A fertile soil in good mechanical condition is the foundation of all success. If manure has not already been provided it will not do to hurry to the nearest stable and buy a supply, for it will be of little use in a garden until thoroughly decomposed so that when it is put on the soil it will be dark colored and without a trace of straw. If the ground has been well enriched in former years bone-meal, guano and chemical fertilizers are of great advantage, but these should be used only as adjuncts to well rotted stable manure. Do not begin to dig or plow while the soil is still wet. The ground should never be disturbed until in such a condition that it will easily pulverize; and when it has been plowed or spaded tender vegetable seeds like those of Cucumbers, Melons, Lima Beans, Okra, Tomatoes or Corn should not be planted in the open ground until warm weather has permanently come, which will not be in this latitude until about the 20th of May. Other vegetables should be planted as soon as possible and the earliest peas should already be in the ground. The American Wonder is the best of the dwarf Peas for family use, but there are some places where this variety refuses to grow. The little round peas should never have a place in the home garden. Of the wrinkled varieties Alpha is among the earliest and is of excellent quality. It is a good plan to make one planting of Alpha as soon as the frost is out of the ground, and then a fortnight later to plant at the same time Alpha and some second early like McLean's Premium Gem, Stratagem for later, and Champion of England for the main crop, and these will follow each other in due succession. The season can be prolonged by later plantings of Champion of England. The seed of Beets, Cabbage, Cauliflower, Parsley, Lettuce, Onions, Parsnips, Spinach, together with the roots of Asparagus, Rhubarb and Horse Radish, should be placed in the ground as early as it can be worked. Tenderer plants like Peppers and Egg Plant, which have been sown under glass, should be looked after and thinned out; they need plenty of room and ventilation on warm days so that they can be hardened. Damping off, owing to the excessive moisture and cloudiness this spring, has been a source of great annoyance. The only remedy for this is abundant ventilation and keeping the soil as dry as is consistent with safety. A sprinkling of clean, dry sand over the soil when the trouble first shows itself is beneficial. The covering should be removed from Rhubarb, Asparagus and Spinach and if the soil is dry enough light cultivation should be given to the surface.

The Flower Border.—Hardy herbaceous plants should be now set out, and so should dormant Roses and other shrubs. Beds of Pansies, Daisies, Forget-me-nots, Auriculas, etc., should be planted out now and they will be in their glory for a month or more. Seed of Sweet Peas, Alyssum, Asters, Candytuft, Larkspur, Poppies, Gaillardias, Coreopsis, Sweet William and the whole range of the hardier flowers can be now sown. Care should be taken to have the ground in fine condition and that the seeds are not buried too deeply. Seeds of the tenderer plants, if sown in the open ground now, will either rot, or if they do come up will make but feeble growth.

Recent Publications.

The Forests of North America.—I.

Die Waldungen von Nordamerika, ihre Holzarten, deren Anbaufähigkeit und forstlicher Werth für Europa im Allgemeinen und Deutschland insbesondere. Von Dr. Heinrich Mayr. M. Rieger, München, 1890 (New York, Steiger & Co., 25 Park Place).

As the sub-title of Dr. Mayr's "Forests of North America" shows, his chief concern in studying our trees was to estimate their probable utility for economic planting in Europe, and especially in Germany. The author's first journey in this country was undertaken by order of the Bavarian Government, while he held the position of *Privat-docent* at the University of Munich. The second time he visited our forests he was on his way to Japan to assume the position, which he now holds, of Professor of Silviculture at the University of Tokio. His book, which was written in Japan, is primarily an official report in the interests of the industries of his fatherland. But, with German thoroughness, he has exhaustively discussed his subject from other points of view as well as from the chief one, and in many respects the work is

the most important which has yet been published on the forests of our country. It is the first which has embodied the observations and conclusions of a scientific forester, trained in all the knowledge of the schools as well as by personal experience in European woodlands, and able to take a point of view at once thoroughly scientific, and, in the best sense of the word, thoroughly practical. In the brief space here at command it is, of course, impossible really to review such a book. Each page as it is turned seems of special importance; there is no chapter to which justice could be done by a short summary; there is more than one of which the value depends upon its fullness of detail, its wealth of illustrative facts; and when the would-be reviewer has carefully read the volume his conclusion is that only a translator could fully explain its excellence and significance. So earnest is the author's interest, as a friend of our people, in the forests upon which our prosperity largely depends, and so conscientiously and wisely has he pointed out what should be done for their preservation, that he well deserves the honor of a translation. Meanwhile all that can here be done is to give a brief indication of the character and arrangement of the volume, together with a promise that, from time to time, its most interesting portions shall be placed before our readers.

It is a large and well printed octavo of 450 pages, with twenty-four pictures in the text, and ten separate plates, a map showing the different zones of vegetation in North America, and a chart giving geographical sections, for comparative use, of the North American, the Asiatic and the European continents. Two of the plates show the leaves and fruit of various North American Oaks, three the leaves and fruit of a number of other deciduous trees, one the fruit and foliage of conifers, two the seeds of conifers, one the anatomical structure of the wood of certain conifers, and one a number of the fungi which afflict our trees.

In the preface Dr. Mayr briefly tells of the inception of his task and the way in which it was prosecuted, renders hearty thanks to all who in this country gave him practical or scientific help, and outlines the scheme of his book. The text proper begins with a discussion of the conditions under which forests exist and general remarks upon forest-flora; and the forests of North America are then described and discussed under different headings. These are: (I.) The General Condition of the North American Forests; (II.) The Size and Divisions of the Forests; (III.) The Products of the Forests; (IV.) The Growth and Quality of North American Forest-trees; (V.) Changes in Forest-Vegetation through the Action of Man; (VI.) Forestry Efforts in North America; (VII.) A Special Consideration of the North American Forest-Flora according to Districts and Species; (VIII.) The Behavior of Exotic Species in North America; (IX.) North American Species from the Standpoint of their Fitness for Cultivation in Europe and especially in Germany, and (X.) from the Standpoint of their Economic Value to the German Forest; (XI.) Scheme for the Planting and Treatment of North American Species as Trees of the German Forest. The work then concludes with a twelfth section or appendix, in which we find information upon the anatomical characteristics of the woods of our conifers; a scheme for the arrangement of Pines (including non-American) according to Natural Sections; tables for the identification of the more important *Cupressinæ* by their young branches and cones, and of the North American Pines by their seeds; a description of the vegetable parasites observed on our forest-trees during the late autumn of 1885 and of 1887; a list of firms from whom the seeds of American forest-trees may be obtained; and a few notes and errata.

Two schemes were open to the writer of a book covering this ground. He might have adopted what we may call a scientific scheme, taking up each species of tree in botanical order and arranging under a single heading all the information he had to give with regard to it. Such a scheme would have been more attractive to the student and lover of trees in themselves, would have avoided the many repetitions and cross references which now increase the bulk of the volume, and would, we think, have been more easily serviceable to the European forester. But, on the other hand, the method Dr. Mayr has in fact adopted gives what the other scheme would not have given—complete pictures of the forest-flora of our different zones of vegetation. Such pictures the reader would otherwise have had to compile in his mind from a multitude of isolated passages. Now what he has thus to compile is the author's information and opinion with regard to any given species which may specially interest him. The scientific student might have preferred the botanical arrangement; but to the general reader, in any part of the world, the actual one will undoubtedly be more attractive. Nor, in his case, are the

repetitions it involves to be regretted. The more important facts are insisted upon, and the more often they are re-told with varying words, the more likely they are to impress the mind of any but a serious student.

And there are innumerable facts and conclusions and counsels in this book with which it would greatly profit the general reader in America to become thoroughly familiar. Nowhere have we read a fuller, clearer or better emphasized account of the damage which has already been done to our forests, which is still being done, and which threatens to continue until there is nothing more to damage; and nowhere a more judicious statement of the certain consequences of its persistence or of the methods which should be adopted to stay it. To a German trained in forest-conservation, the scenes now presented by our woodlands, and the scenes they suggest to an imagination which looks even fifty years ahead, may well have seemed as incomprehensible as horrifying. It is in truth a tragic panorama, and Dr. Mayr paints it in words which, while carefully based on actual facts and never falling into hyperbole or mere declamation, are of tragic intensity. As we read the chapter with the seemingly peaceful heading, "General Condition of the North American Forests," we seem to be assisting at a reckless, senseless conflict at once murderous and suicidal. We see a people, now the richest in the world, which, for the sake of a little more immediate wealth—or often for the sake of nothing but mere destruction—is sweeping away the most magnificent of Nature's gifts, and one that can never be replaced, is hopelessly ruining the aspect of vast areas of beautiful country, and at the same time is working with frightful celerity for its own ultimate impoverishment. Most of the facts and figures and descriptions which Dr. Mayr gives in drawing this general picture have long been painfully apparent to a few Americans, and have often been reiterated by them to the deaf ears of their countrymen at large. But as here massed together, as they appeared to a fresh and sagacious eye, they gain a new significance and stand out in even darker colors. It seems as though, could this chapter be translated and spread abroad in a million copies or so, the whole people would rise in a horrified awakening and make an appeal for self-preservation which even the dullest legislative body could not resist. To quote anything he says would be useless here; our readers, we trust, already stand at Dr. Mayr's point of view; and, we repeat, it is the massing of his facts which gives them their singular vividness. It would be painful to think of the spectacle we must present, as thus reported, in the eyes of German readers, were not the practical bearing of the matter on our own future so vital that room is not left for any minor sting.

It should not be supposed, however, that Dr. Mayr writes in an unfriendly or even unsympathetic spirit. As he never speaks without facts, so he never exaggerates in drawing conclusions. He is quick to note all possible excuses which may be made or fancied for our madness, even to the fact that we are so largely the offspring of that English race which lives in a little level world where forests do not exist and the need of them is not felt; and he is diligent in recording all the little public efforts that have been made in the way of reform, and all the private enterprises which indicate that there are individuals among us who know the truth and are anxious that it should be impressed upon the people at large. He praises the Arnold Arboretum heartily; and his appreciation of the Jesup Collection of Woods in the Museum of Natural History in this city will go far to prove to its donor and the officials of the institution that their work has been well done. He describes the scope and arrangement of the collection, notes the giant dimensions of some of the specimens, and says, "Certainly nothing has been spared in securing them; such colossal specimens can be shown by no other museum in the world." And, of course, he appreciates the fact that this collection, the dendrological herbarium at Brookline and the neighboring Arnold Arboretum each gains in value by the complementary usefulness of the others.

Yet, after making all possible deductions from the picture of blind ravage which he draws, we can fancy Dr. Mayr laying down his pen with a sigh of despair—so few and small are the bright spots, so alarming is the blackness of the picture as a whole. Some day, of course, as he says and we all know, there will come enlightenment and reform. But how much unavailing remorse will mingle with them, even though they come very soon; and is it not possible that they will come when practically too late? It is impossible to calculate, says our unwilling critic, whether complete forest-destruction, such as we see in the Holy Land and in certain parts of southern Europe, will be reached in fifty years, should our present methods continue, or will need a couple of decades more.

When he adds, it is unfortunately improbable that within the next few decades our country will be so far advanced as to take "systematic care of its magnificent forest-treasures," the suggested prospect may well excite alarm. No passages in his book, by the way, are more interesting and instructive than those which show why, when the primeval forest is destroyed, it can never be replaced by man or renew itself in man's vicinity; but these we reserve for full translation at another time. We must once more explain, however, Dr. Mayr's exact attitude. He is not an enthusiast, who, in his love for the forest, forgets the needs or the right desires of man. He does not ask that everywhere the forest shall be preserved, nor make the beauty of the landscape the prime reason for its protection. On all arable low lands, he explicitly says, the forests should and must be cut away; and their preservation in the mountains he shows of course to be as truly in the interests of man as in those of the trees themselves.

Correspondence.

Why Not Legislate Against the Black Knot?

To the Editor of GARDEN AND FOREST:

Sir.—There are some good reasons for legislating against the Black Knot (*Plowrightia morbosa*) of the Plum and Cherry trees. In the first place the fungus is beyond question extremely destructive; whole orchards of large size in many parts of the country have been abandoned because of this parasitic plague. Secondly, it is a conspicuous disease and during the half of the year when the trees are defoliated the knots can be found without the least difficulty. Any attempts to shield the trouble, on the part of the owner, would be fruitless even if he should care to preserve the curse. In the third place, the remedy is the very heroic one of the knife, and easily, safely and with certainty applied. There may be some compounds put upon the diseased parts that will kill the fungus, but it is so deeply seated that when a twig is thoroughly infested there is little left for the fruit grower to do but cut away and burn the black excrescences. If a tree is badly attacked the wisest method is to cut down bodily and destroy it by fire. Finally when once the old knots are cleared out it will be an easy matter to keep the fungus from gaining a fresh foothold.

There are many trees which are literally covered with knots and have been for years; trees which bear no fruit, and never will, and they are worse than mere monuments of carelessness, for they propagate and perpetuate a disease that renders Plum-raising almost an impossibility in their neighborhood. Sometimes these old distorted trees are upon the roadside where any passing lad can pull off and carry to his own home one of these malformations to become a new center of infection. But these knots do not need to be transported to produce infection, for the millions of spores developed in the spring, while too small to be seen, pass long distances with the winds and thus spread the disease.

There are several fungus diseases against which the state legislatures or the national congress might pass enactments fully as wholesome and beneficial as those for the control of the diseases of animals, but few of them offer so many favorable points for successful legislation as the Black Knot—the scourge of Plum and Cherry growers in many localities. The law should include, to be effective, all Wild Plum and Cherry trees that are breeding places of the pest.

Byron D. Halsted.

Public Forest Associations.

To the Editor of GARDEN AND FOREST:

Sir.—Apropos of the plans for saving the Waverly Oaks, I should like to urge again a general proposition for the accomplishment of public purposes of this kind, which was broached some months ago in another place, and which seems to me entirely practicable. It is that there shall be organized and chartered in the State of Massachusetts a public forest association, whose principal object—no doubt it would be well to make it its only object—would be the acquisition of the title to tracts or lots of land which, from their natural beauty or picturesque significance, or from the fact that they include trees or plants which are of historical or botanical importance, it is desirable to preserve for the public benefit.

Such an association, if established in the proper way, could hardly lack members; and the means necessary for purchases, provided the power to condemn land was not given to it, could be obtained through subscriptions from time to time, or

through endowments which the wealthy would surely provide when such a work had attained the repute and honor which it would deserve.

The model of such an association is found in the Lynn Public Forest Association, whose work, thanks to the acquisition of nearly the whole of the great Lynn Woods by the City of Lynn, is now rendered unnecessary, or, rather, adequately crowned; for the creation of the magnificent Lynn park of about 1,200 acres is really the outcome of the work of this Society. It was this body which succeeded in checking the destruction of the beautiful Hemlock timber in the deep glen on Penny Brook, and which rescued several other sylvan spots in the same neighborhood from profanation simply by buying out the profaners. And the public spirit which its work stimulated no doubt made possible the reservation of so splendid a domain for public use in perpetuity.

Apply the principle, so successful in one small city, to the commonwealth, to any state or to the nation. Let public-spirited men and women unite in such an association, and seek charter and authority to acquire property under proper restrictions. I know of no cause in which the power of eminent domain could be invoked more righteously than in protecting from private destruction the exceptional and striking natural beauties which are equally dear to all, or in preserving the groves or trees around which the people's history or legends cluster. But even if such an association had not authority to acquire property by condemnation, the possession of a considerable emergency fund, accumulated in advance and ready to be judiciously drawn upon at once by alert men, would in a great number of cases prevent the defacement of scenery, or the destruction of woods or individual trees which centuries could not replace.

The best work that has ever been done in this country, in the way of reform and public enlightenment and education, has been at least put in motion, if not completely accomplished, by private effort represented in associations. It seems to be almost idle to try to get Congress or Legislatures to do anything toward saving the great forest-domains. But is it not possible to make use of the great instrumentality of voluntary association to save the spared monuments of a sylvan past still remaining to us?

The Rest of Plants.

To the Editor of GARDEN AND FOREST :

Sir.—1. Do all plants have, or require, an annual "resting-period"? If so, how much is meant by that term?

2. Is it true of all the ordinary window-plants, such as Geraniums, Fuchsias, Gloxinias, Shrubby Begonias, etc., that they require a season of retirement, or letting alone, in some part of the year?

3. Can any general rules or directions be given for thus "resting" plants which will be of service to the amateur window-gardener; or must one know the habits, the natural resting-season, of each plant or species?

4. Can you name any work or article already in print which treats of this subject in any detailed way?

Whitewater, Wis.

A. S.

1. So far as I know, all perennial plants undergo a period of "rest." It is not certain, however, that this "rest" is in any sense a recuperation or recreation to the plant. It appears to be a hereditary trait, induced by natural environment, a means by which the plant resists untoward circumstances of climate. These untoward circumstances in nature are variations in temperature or moisture, or both. In the dry seasons of the tropics plants "rest" in much the same manner as in northern winters. Any attempt in culture to overcome the "resting-period" is apt to injure the plant, from the fact that any energy used in the partial or abnormal development may be subtracted from subsequent growth or development.

2. I know of no investigations to show that this hereditary trait of plants has ever been entirely overcome by culture. Our window-plants still demand "rest."

3. In practice, however, it is in every way more desirable to start ordinary window-plants anew every year than to attempt to handle old ones. Young plants are vigorous, healthy, floriferous and economical of space. Started in late winter or in spring, they will bloom the following winter, after which they should be discarded. But if old plants are retained, I cannot state any general rule for

"resting" which will apply, with any value, to all kinds.

4. The best literature of the practical application of the "resting-period" to plants is found under the discussions of the various species, in garden manuals. L. H. Bailey.

The Cork-wings on the Sweet Gum.

To the Editor of GARDEN AND FOREST :

Sir.—The Sweet Gum, *Liquidambar styraciflua*, which, from its handsome habit of growth and rich autumnal coloring, has been extensively planted in Tower Grove Park, in this city, shows a good deal of variability in the development of "cork-wings" on its branches—a development for which it is noted, and which has received considerable attention from histologists, one of the latest of whom, Miss E. L. Gregory, has given an extended account of it in the *Botanical Gazette* for 1888 and 1889.

While it appears to be the rule for the branches to bear two or more prominent wings on their upper side (this position, according to Miss Gregory, being peculiar to this species), it is noticeable that not far from one-half of the trees in the park named are destitute of such wings, while a few others possess few of them. The trees compared are of the same age, have grown under similar conditions, and no observable reason for the difference noted is to be seen, the winged and wingless specimens occurring with no regularity. These trees are now about seventeen years old, and the difference referred to appears to depend upon inherent peculiarities of the individuals, since the smooth trees have always been destitute of wings, while these appendages were early developed in the others. The different appearance of the two sorts of trees is very striking when the leaves are off in winter. It is quite as evident in considerably larger and older trees than those illustrated.

Botanic Garden, St. Louis.

Wm. Trelease.

[Photographs which accompanied this letter clearly show the differences described by Professor Trelease.—ED.]

Gordonia Altamaha.

To the Editor of GARDEN AND FOREST :

Sir.—The best specimen of *Gordonia Altamaha* in the District of Columbia grows in Lafayette Square, in front of the White House. The tree, or rather large shrub, which is in vigorous health, is nearly, or quite, twenty feet high and ten feet through. I supplied this as a small plant about the year 1855. It grows and flowers freely, and has not been injured by cold. There are few, if any, other specimens about the city, except those growing on my nursery grounds, on a dry, rich bottom land, where they grow and flourish with great vigor. They pass through ordinary winters without harm, but in one severe season the young growths were killed. The plants, however, all quickly recovered.

I doubt whether this *Gordonia* will succeed much farther north, unless planted in a warm, sheltered position. I know of no other tree or shrub, that blooms at the same season, which can compare with it in beauty. Its pure white flowers are produced in July, and appear abundantly up to October, and even on till the middle of that month. The foliage assumes, in autumn, a rich crimson tint, which is quite distinct and striking.

Washington, D. C.

John Saul.

Notes.

The Maples growing in the gulches on the western slope of the Sierra Nevada have been tapped this year, and although they do not yield such an abundant flow as the Sugar Maple, the sap is said to be sweeter and makes finely-flavored sugar.

It is said that no less than 7,769 school-gardens exist in Austria, not including the sister kingdom of Hungary. They are connected with both private and public schools, are used for purposes of practical instruction in horticulture and tree-growing, and often contain botanical museums and bee-hives.

One of the most interesting flowers we have seen this spring is the white *Chionodoxa*, which Mr. Gerard has grown from bulbs sent to him last autumn from Asia Minor, by Mr. Whittall. The color is pure and the flowers are held well up above the foliage. Mingled with the deep blue of the ordinary kind the effect will be very beautiful. White flowers of this class, too, are rare after the Snowdrops are over. These plants are very rare in their native home, and Mr. Gerard's experiments to ascertain whether they will come true from seed will be watched with interest.

Another instance of the way in which our florists now devote themselves, very often, to raising large quantities of a single kind of flower is found in a note, dated Springfield, Massachusetts, which was recently published in the *American Florist*. "I grow Carnations only," said the writer, "and last season I cut 26,000 blooms from 700 plants of Grace Wilder. I now have 1,300 plants."

A lady who read a paper at the meeting of the American Horticultural Society, which was held in February at Austin, Texas, recommended that the effort to agree upon a "national flower" should be abandoned; but that instead each state should select a flower for itself. Thus far the advice seems good enough, if, indeed, the subject has any real hold on popular interest. But when we are told, furthermore, that on occasions of national significance all these "state flowers" may be massed in a great bouquet or garland, the picture presented to the imagination is not very agreeable.

German horticultural papers speak highly of a variety of *Begonia florida incomparabilis* which has been named "Hofgärtner Pettera" after its introducer, the gardener of Duke Philip of Wurtemberg, at Gmünden. The flowers, which are dark carmine, "completely cover the plant;" but its great peculiarity is the color of the leaves, which, when exposed to full sunshine, "become a deep blood-red, while the stem and leaf-stalks are coral-red." It is recommended as a valuable addition to the plants now used for carpet-bedding and for multicolored groups.

A peculiarity of the plants producing what we call gourds or calabashes is the musk-like odor that most of them give out when their leaves are pinched. We generally look upon a gourd as something unsuitable for the table; but Dr. Harris states that when cooked several of the varieties of Syria, Japan and Brazil are quite palatable while young, especially those which grow long, thin and green, like the Hercules Club. The fruit which furnishes the reticulated skeleton used as a bathing-scrubber and in making beautiful bonnets is in habit and growth a Cucumber (*Cucumis reticulatus*), although sometimes called a "Dish-cloth Gourd" from one of its uses in our Gulf States. In India the natives eat one of the varieties when quite young; but of a dozen varieties grown by Dr. Harris in Philadelphia none were tempting to the appetite.

A corporation called "The Blue Mountain Forest Park Association" has been formed at Newport, New Hampshire, its President being Mr. Austin Corbin, of this city, whose summer home lies in that region. The purposes of the Association are to breed American game and fish, to cultivate and properly administer the forests, and to form and beautify parks and avenues. Seventeen head of buffalo have been turned out on a "range" which embraces about 10,000 acres, and it is hoped that the race may thus be preserved from extinction. The good done by such an association, however, will spread far beyond its own property, for it will doubtless incite the citizens of other localities to imitation, and must help to prove to the people at large that our forests are worth preserving, and that the adornment of country neighborhoods should be systematically undertaken.

We have received the first number of *Zoe*, a new biological journal to be published monthly in San Francisco. It is intended as a "medium for recording in accessible form the numerous, often unconnected observations, pertaining more particularly to the western part of North America, made by amateurs as well as by working naturalists." The name of the editor does not appear in the prospectus, but contributions are promised, and many of the promises are fulfilled in the first number, by articles from many of the best known naturalists of the Pacific States. The first number contains botanical notes by both Mr. and Mrs. T. S. Brandegee, and the first of a series of important articles on the naturalized plants of southern California, by Mr. S. B. Parish. *Zoe* is in magazine form, in octavo, and the first number contains thirty-two handsomely printed pages. It is published by the Zoe Publishing Co., of San Francisco, and the annual subscription is two dollars.

One of the most perfect trees in the United States stands behind the old Drayton Manor House on the Ashley River, not very far from Charleston, South Carolina. It is a Live Oak. The trunk girths, at five feet from the ground, nearly twenty-five feet, and the main branches, which shoot out at right angles from the trunk at the height of ten feet above the ground, have a spread of one hundred and twenty and one hundred and thirty feet, and form a dense, symmetrical, flat head of indescribable beauty and impressiveness. There are larger Live Oaks to be seen, but it is rare to find

one of the age and size of the Drayton tree of such perfect shape and in such good health. There is nothing about the tree to indicate very great age, and as it is a well known fact that the Live Oak grows in good soil with extreme rapidity, it is not improbable that the two centuries during which the Drayton family have occupied the Manor House may cover the span of its existence.

Writing on "The Slave Trade in the Congo Basin," in the April number of the *Century Magazine*, Mr. E. J. Glave says that nature has, in the case of the African, met the universal desire for a drink stronger than water by providing him with the juice of the Palm-tree, "a most palatable beverage, resembling when fresh a very strong lemon soda, but intoxicating in its effects. . . . The villagers in charge of this particular industry climb the tree, trim away some of the leaves, and then bore three or four holes, about half an inch in diameter, at the base of the frond, to the heart of the tree." A small gourd is placed beneath each of these holes, and receives during the day about half a pint of juice. "The contents of these gourds are collected every morning. This beverage is called by the natives *malafu*, and is well known to all European travelers as Palm-wine." From the author's accounts of the drunken revels which he witnessed, it seems to be as potent, in its ultimate effects, as the most civilized of fermented drinks.

Odontoglossum Pescatorei is the rival of *O. crispum* as a garden Orchid. In their cultural requirements and in general habit they are alike, whilst in attractiveness there is little to choose between them. Both species have revealed under cultivation an extraordinary range in the size, form and marking of their flowers. Now and again a variety of startling character appears, and if placed in the market fetches a sensational price, as, for example, Veitch's variety of *O. crispum* and Veitch's variety of *O. Pescatorei*, both of which are in Baron Schroöder's famous collection. The last sensational feat has been the production of an inflorescence by *O. Pescatorei*, upon which no less than 130 blooms were borne! The length of the panicle was four and a half feet, or more than double the maximum length given in Veitch's *Orchid Manual*. It bore fourteen branches, which again ramified. The plant must be of extraordinary vigor, as its pseudo-bulbs are described as being as large as large hens' eggs. It is in the collection of Mr. J. B. Merriles, Reading, and was grown by his gardener, George Russell.

We have received from Mr. O. C. Simonds, Superintendent of Graceland Cemetery, Chicago, a series of photographs illustrating the method of transplanting large trees. Of two trees moved together the larger was sixty feet high, with a spread of branches of sixty feet. The roots were taken up in a circle of about the same diameter, tied up in bundles, wrapped in canvas and kept moist. The trees measure respectively seven feet three inches and six feet in circumference, the measurements being taken at three feet above the ground. The earth was retained about the roots for some distance from the trees, which were moved in an upright position. The planting was completed on the 4th of May, 1889. The trees grew nicely during last season, and Mr. Simonds believes they will become as firmly established as they were in the woods from which they were taken, although it is yet too early to speak with entire confidence as to the result. The trees were moved on rollers nearly a mile in an upright position, stayed upon a heavy frame-work of timber, and the cost was between five and six hundred dollars.

According to a correspondent of *Gartenflora*, the splendid crops of Hyacinths which are grown in the vicinity of Haarlem, in Holland, require a careful preparation of the soil. A field which the following autumn is to be planted with bulbs is worked over during the winter to a depth of three feet, in order that the upper soil, in which bulbs have already been grown, may be thoroughly replaced by fresh sand; for it is almost pure sand which forms these fields along the dunes. Simple cow-manure is then applied, and Potatoes are planted, and after these are harvested the soil is again worked over. About the beginning of September the bulbs are planted and covered with a layer of sea-weed, which is removed early in the spring. The yellowish leaves which have sprouted under the mulch quickly turn a deep green, and by the middle of April the flowers spread their immense many-colored carpet before the eye. As soon as they begin to fade they are cut off to direct all the strength of the plant toward maturing the bulbs. Formerly the cut flowers were sold, largely for the English market; but this sale so injured the demand for bulbs that, by agreement among the growers, it has been abandoned.

An English Forest.

AN old English forest is a very beautiful and interesting thing, although, judged by the standard of modern forest science, it is practically a useless encumbrance of the earth, to be cleared away that the ground it occupies may be replanted to better advantage. Such a forest is that of Sherwood, in Nottinghamshire, the most famous and historically the most interesting of all the remnants of the ancient forest-covering of Britain. A view taken in this forest appears in our illustration on page 203, and represents a portion of the high-road leading through "Bircklands," as one part of Sherwood Forest is called, because Birches grow in great numbers among the old Oaks. The forest-floor is densely covered with Bracken (*Pteris aquilina*), making a charming carpet among the trees, which stand singly, often with wide places between them and unsurrounded with young trees growing up to replace them. Deer and rabbits have frequented Sherwood Forest for centuries, and it has been pastured at times and sadly neglected and abused; every seedling-tree, as fast as it appears among the Ferns, is nibbled off and destroyed, and no successors to the great old trees have been allowed to grow up to take their place when they have lived out their long lives. Very few of the old trees are left; multitudes of them fell a century or more ago to replenish the purses of needy noblemen, and time has laid a heavy hand upon those which escaped. And now this forest, which is really not a forest at all, but rather a thickly planted park, bears about the same relation to a modern European forest that an English farm, with its wide, useless hedgerows, its broad branched Elms shading the ground, sucking up moisture from the earth and using up plant food, its game carefully protected to feed upon the crops, and all its wasteful methods of pasturage, bears to a modern German farm, in which every inch of ground is made productive and not one ounce of anything is wasted.

A drive through Sherwood Forest is one of the most delightful things an American can do in England, although he will not learn much about forestry on his trip or see many things which can be applied in his every-day life at

home. A visit to Sherwood Forest and "the Dukeries," as a number of country places made in what was once a part of the old forest and lying adjacent to each other are called, is a common English holiday trip for people living in the cities of the midland counties, and thousands make it every year. The excursion is easily made from the town of Worksop, in Nottinghamshire, and a day is needed to make the circuit of thirty miles through the different estates and the remnants of the forest. Two or three days, however, can be well employed in the neighborhood of Worksop if the visitor is interested in gardens and in fine houses as well as in old trees. One may see in these two or three days Worksop Manor and park, lying close by the town—a fine park, now the property of the Duke of Newcastle, the house, however, much reduced by fire from its old estate. It was the home of the Earls of Shrewsbury, and stout Bess of Hardwick built the mansion or finished it, and ruled over its destinies, as she did in one way or another over all the great families of the county. Mary Queen of Scots was once a prisoner in this house. There are a few fine trees in the park, including a group of noble Oaks not far from the mansion. A little beyond Worksop Manor the high-road leads into the enclosure of the park of Welbeck Abbey, where the visitor will find the winners of two successive Derbys and the most successful breeding establishment in the history of the English turf.

Just beyond Welbeck is Clumber, the seat of the Duke of Newcastle. The house is low and badly placed, and dwarfed, moreover, by the ugly church just completed, which is placed too near the mansion, with whose architecture it does not harmonize. The handsome terrace joining the house with the lake is one of the most successful in England; and the view across the lake to the rolling park beyond is very fine. There are noble trees in the pleasure grounds and in the park, and the lake, with its margins lined with wild plants and stocked with wild fowl, is certainly a most wonderful imitation of nature. The view of the mansion from one of the drives where it crosses a narrow arm of the lake on an old arched stone bridge is deservedly famous. The house contains many fine pictures and other works of art. What will strike, perhaps, the American visitor to Clumber are the countless thousands of rabbits running about every part of the place, which seems completely undermined with their burrows. The park contains no herds of deer, which abound at Welbeck, and in Thoresby Park, which is just beyond Clumber, and from which it is separated by two pairs of gates.

Thoresby, the seat of Earl Manvers, by far the most beautiful of "the Dukeries," and one of the most interesting places in all England, has a noble new Elizabethan mansion, built on high ground, overlooking the large artificial lake, close by which the old house stood. The park is twelve miles round, and contains many interesting and exciting views and many noble trees. Not far from the house is a small-leaved Linden-tree not easily matched anywhere, and across the lake is an avenue a mile long of splendid old Chestnut-trees of immense size, forming a long vista which loses itself in the mysterious depths of Sherwood Forest beyond. In the shubberies near the house, although not very long planted, are the finest specimens of the Hemlock-tree of the high Sierra Nevada (*Tsuga Pattoniana*) which can be seen in Europe. The present Earl Manvers is a planter of trees, as the young plantations all over the estate bear witness; and at one point the drive leads through a real forest of Beech-trees, with tall, straight trunks, which a German forest-master would not be ashamed of. Deer wander through the park right up to the terrace-wall and to the gates of the courtyard, and from the house great flocks of sheep and herds of cattle can be seen feeding under the park trees, giving life and variety to the scene and adding much to its attractiveness.

Passing out of Thoresby Park gates the road leads directly into Sherwood Forest at the point where the view in our illustration was made. Then it stretches through

"Bilhagh" and "Bircklands," under the sturdy branches of the "Major Oak" and by some of its hardly less famous companions, and then, leaving the forest and skirting the park and woods of Welbeck, it returns to Worksop through rich farm-lands held by tenants of the Duke of Portland. Newsted Abbey, the home of Byron, is within easy driving distance of Worksop, and forty miles away in the other direction is Chatsworth, the seat of the Duke of Devonshire.

This short sketch is not meant as an account of Sherwood Forest or of "the Dukeries." They are described over and over again in books which treat of rural England, and in the pages of English journals of horticulture. Our object in alluding to them is to remind our readers that if they visit England they can see in the neighborhood of Worksop, better perhaps and more easily than anywhere else, what rural life means to English noblemen.

THE great advance in horticulture during the last twenty or thirty years is due largely to the sustained and intelligent efforts of those specialists who have devoted themselves to the study and improvement of particular classes of plants. Such men, for obvious reasons, have been more numerous in Europe, particularly in England, than they have been in this country. We can point, however, to conspicuous instances of long continued horticultural experiments in America, and as wealth and leisure increases here they will probably become more frequent than they have been. Mr. Hunnewell, who relates in another column the conclusions he has reached from long years of patient cultivation of the Rhododendron, shows us what an individual interested in a particular class of plants can accomplish in increasing the stock of available knowledge relating to his favorites. Mr. Hunnewell has for nearly forty years been the most munificent patron of horticulture in America, and his gardens at Wellesley, in Massachusetts, are famous from one end of the land to the other. But unlike many another horticultural Mæcenæ, he does not content himself with the mere lavishing of money in gardening, but practices the art himself, knowing his plants and all their requirements thoroughly, and devoting himself year after year, and often in the face of great disappointments, to the study of his favorite Rhododendrons and of the great collection of conifers for which his garden is also celebrated.

When the cultivation of Rhododendrons was first undertaken at Wellesley little was practically known of the proper methods of growing them in the United States, and nothing at all of the sorts suited to our climate. To give a full and fair test to all attainable varieties of these plants demanded rare steadiness of purpose, but Mr. Hunnewell's patient labors were renewed year after year with never flagging zeal and enthusiasm. When his first Rhododendrons were planted, it was believed by most Americans who knew anything whatever about them that any effort to cultivate them here in the open air would be hopelessly wasted. But forty years of experiment has proved that many of the very best varieties will grow in New England as readily as a Lilac or a Guelder Rose, if certain simple cultural conditions are supplied. That such men as Mr. Hunnewell, generous, public-spirited and patient in pursuit of knowledge, appear occasionally among us, is certainly the most hopeful sign that American horticulture is advancing to the broader and better fields we confidently predict for it.

THE proposal of the Park Board of this city to remove the collection of animals in Central Park from their present quarters to a larger space of open meadow on the opposite side of the park has called forth a vigorous protest from the entire press of New York. The objections to this scheme are not based on the opinion that the ground now occupied by the menagerie is a suitable one, nor on the assumption that a good zoological garden is not altogether a worthy object to strive for, but on the conviction that the open spaces of the park are too valuable to be sacrificed to

any exhibition of the sort, however desirable in itself. Our own belief is that this conservative view cannot be too strenuously insisted upon. It is these tranquil meadow surfaces which make the park efficient as a refreshment and a relief from the rigid lines of streets and buildings; and the paramount duty of all who have any influence in these matters is to guard against any possible encroachment upon these areas of greensward and their border of trees. These open meadows, of which there are now too few, and which were created at great expense, constitute the primary and essential value of the park, and to obliterate them is a practical confiscation of public property. It is encouraging to find that every attempt on the part of any special interest to occupy and possess these grassy openings gives occasion for the people and the press of the city to demonstrate how profound is their appreciation of the true function and the highest purpose of the park.

Native Shrubs of California.—III.

Garrya elliptica, Dougl. ("Bot. Reg.," t. 1686). From the figure given in the "Botanical Register," more than fifty years ago, taken from a specimen which had flowered in England, one would not infer that the species deserved mention among the really very ornamental shrubs of California. Perhaps it did not find in England a congenial climate. In its native localities among the Coast Mountains, growing, in clumps, from six to ten feet high, with its dark green, leathery, wavy-margined foliage, it is never unsightly; while at flowering time it appears very uniquely beautiful. The inflorescence, while amentaceous, and therefore like that of Alders and Birches in kind, is of a much more showy character. The tassels, those of the male shrub being commonly eight or ten inches long, very slender, and of a pale green which harmonizes well with the dark hue of the foliage, are hung forth from two to four or five in a place, at the ends of all the branches and branchlets; and being of such length, some of them fall across lower branches and often hang in festoons, draping most gracefully and attractively the whole bush. The flowering occurs usually in early February, after the first week of mild, sunny spring weather; and the long light chains of pale olive green, naturally of only ten days' duration at best, are sure to be gathered from the bushes, almost before their full development, by afternoon strollers in quest of earliest wild flowers.

One or two other species of *Garrya*, found southward in the state, or in the mountains of the interior, are less ornamental; but by virtue of the strongly tonic property of their bark, they are well known to miners and mountaineers, who employ them as a remedy in ague and intermittent fevers. The bark of the Cornel or Dogwood of the Atlantic States has the same qualities; and there are botanical systematists who consider the *Garrya* and the *Cornus* as belonging to the same family, although they bear not the least external resemblance to each other. All the *Garryas* have, however, the same fine-grained, very hard wood as the Cornel. But for its uniquely beautiful appearance when in flower our *Garrya elliptica* deserves a conspicuous place in every shrubbery. Lindley described it as hardy in England; but it is doubtful whether it would endure well the dry cold of the New England winter.

Ribes tenuiflorum, Lindl. ("Bot. Reg.," t. 1274). I must speak first of the bibliography of this, our Californian Yellow Currant; for I have long perceived that all American writers of the present generation confuse it with the Missouri Currant (*R. aureum*). The two species are entirely distinct, as I have clearly seen ever since my earliest years in California. The last-named does not grow either in California or anywhere west of the Rocky Mountains. The former is found along the eastern bases of the Colorado mountains and for some distance eastward. The confusion of the two began with Pursh, who, in 1814, had both in mind when he described his *R. aureum*. According to Lindley, Pursh's dried specimens were of the far western shrub from the Columbia River-region, not then introduced into England, and his description was drawn up from living bushes of the true Missouri Currant, at that time already in cultivation there. Nuttall had in 1818 indicated that he considered it to be two varieties of the *R. aureum*; but Lindley in 1829 made clear the specific differences, and gave the name *R. tenuiflorum* to the Pacific coast species, reserving the name *R. aureum* for the one then best known, giving as his reason the fact that this had been the shrub from which Pursh had drawn up his specific character. Both species are figured in the "Botanical Register," *R. aureum*, at t. 125; but they are represented in flower only; and if these plates

exhibiting mere branches in leaf and flower had left nothing untold, botanists would have been excused for treating them as one species. The essential differences between them, apart from considerations of geographical distribution, reside in certain strong characteristics of the flowers and fruits. The sole recommendation of the old and true *R. aureum*, or Missouri Currant, is the delicious spicy fragrance of its flowers. *R. tenuiflorum*, all the way from middle California to the British boundary and across the country to Colorado, has flowers entirely scentless. Its berries are large, of a beautiful amber color, deepening to a paler than cherry-red in fullest maturity, and have an acidulous taste without aroma. Those of the real *R. aureum* are smaller, black, sweet and with a decided black currant flavor.

The Pacific species grows ordinarily to twice or thrice the size of the eastern, and its fruit is valued, even in the wild state, in those remote, still sparsely-settled and little cultivated parts of northern California where it abounds. It is probable that under cultivation it would rise to a place of some importance. But, as above intimated, it is entirely destitute of that one quality, the rich odor of the flowers, which has made its more easterly ally a universal favorite in spite of the worthlessness of its fruit.

Edward L. Greene.

The Woods in Spring.

WHEN the army of white-throats and Savannah sparrows, in their migrations, have flown farther northward, and the "chippies" have become more abundant; when a few "chebecs" and "towhees" are heard introducing themselves to the passers-by, just before the bobolinks and orioles arrive, it may be called the misty season in the woods. You can name no special date when it is at its height, for it comes from the buds so gradually and ends in the larger, coarser spray with such slowly measured growth; but while it lasts the view of the young foliage, lingering on the tangled network of twig and branch, like variously colored scraps of vapor, is, indeed, charming.

No system of color language can describe accurately the various shades of the early dresses of the trees. Many of the hues are softened and subdued, in contrast to the gaudy colors of autumn. Green, in its many tints, is from the first put on numerous species. How becoming are the Alders and the Birches in their fresh, new trimming! The leaves of the Oaks, Maples and Hickories, just unfolding from the buds and flecking the sky with the mellow stains of yellows, reds and browns, are especially attractive. The conditions and surroundings of the trees have much to do in painting the foliage before the chlorophyll has dyed it for its summer's work. The saplings and sprouts of the White Oak are decked with scraps of maroon velvet cut into the regular established patterns, while the leaves of older trees of the same species, on higher ground, are often the color of amber or of half-ripe lemons. The evenly plicated leaves of the Wild Cherry shine like bronze in the sun. Here and there the Large-Toothed Aspens have arrayed themselves in white silky-wool attire, and, as they rise like clouds in fleecy masses amid the early spring foliage of the hard-wood trees, they form very conspicuous objects in the forest.

How exquisitely tender and transparent is the new leaf of the American Basswood! I can hardly bear to look through it at the sun. When it is closely laid on paper, writing can easily be seen through. Viewed in the light it assumes a yellowish cast, and you not only see the slender forked veins, extended at regular intervals from the midrib, but hundreds of gossamer cross lines, like those of spiders' webs, which form the frame-work of the delicate structure. Its shape is beautiful, with sweeps and curves, and its edges are fringed with the finest teeth. What special wood fairy has been appointed to give it such elegant proportions and to cut all of the leaves of the *Tiliaceæ* into the peculiar oblique, heart-shaped pattern? The largest lobes at the bases are invariably placed toward the young shoots, and the leaves are arranged upon them so as to secure the greatest amount of light and air.

The Beeches answer to the call of the sun a few days later than the Basswoods. A copse yonder on the hill-side is just beginning to put out its broidery. Little mouse-ears of leaves, clothed with silken hairs, are unfolding from the brown, rusty scales and lengthened buds; yet, curiously enough, the leaves on the twigs of a few saplings that touch the boles of the larger trees are already more than half grown! Was it the partial shelter in which the buds were placed during the winter that caused them to gain such a start? The Beech-leaves are formed into the most elegant designs. How fresh and beautiful these premature ones appear against the smooth, ashen-gray bark of the old trunks. They are ovals, pointed and evenly

scalloped. The straight prominent veins on the under surfaces, running out to the very tips of the salient teeth, are drawn as with a rule. The arrangement of these ribs, however, is inclined to vary. In some specimens these nerves are opposite along the basal half of the midrib, but become alternate toward the point. Some are alternate at the base, but become opposite half way up, while on other leaves the ribs are alternate or opposite throughout the entire length.

The Dogwoods, or Cornels, too, are putting out. There is a peculiar physiognomy about the leaves of the species, though it can hardly be described, which at once shows to the observing rambler their Cornus blood. All of them have entire margins and are oval-shaped and pointed.

Along the swampy shore of a pond, where on one side rises abruptly a rocky slope studded with tall, straight Chestnut-trunks, I have paused to note a small tree among the boulders which is not very common in the northern and middle New England woods. It is the flowering Dogwood, *Cornus florida*, a big brother to the dwarf Bunch-berry. With the exception of its humble relative it is the only species here that has its flowers in close heads. These heads are surrounded by four large snow-white, corolla-like, heart-shaped leaves that appear some time before the little greenish yellow flowers open, and, when viewed amidst the young foliage or against the gray background of boles, ledges and the dead leaves of the forest-floor, present a very striking appearance. It is a notable example of those kinds of plants that throw out their signal flags to the honey gathering insects. It knows the importance of showy advertisement. Were it not for these conspicuous flyers the early bees and moths would pass them by unnoticed, and thus, by the neglect of cross fertilization, render the seeds and fruit less healthy and vigorous. But how quickly the leaf builders work. Before May has ended many of the leaves have attained their full growth and spread themselves along the branchlets in huge green flakes and slanting pinnacles that swing in the breeze as if they delighted in their luxuriousness; every shrub and tree yields foliage after its kind. There are patterns of hearts, rounds, ovals, spatells, spears and shields. Some are smooth and polished, others hairy and crimped, some with their edges entire or cut into hundreds of different pretty borders; each species of plant taking on the form, size and texture of leaf according to its "peculiar structure and organization, habits and requirements."

Horace Lunt.

The Peruvian or American Potato.

THIS most important and valuable of the edible *Solanaceæ* is very erroneously denominated "Irish" in our census reports. Virginia has a certain claim to be considered the mother of the White Potato, but the vegetable in its present improved state owes more to its Peruvian and Chilian parentage than its Virginian. Much is also due to changes produced in the tuber by different climates and soils, which are in themselves a curious and interesting study. That our present Potato is a development from one wild ancestor having several sub-varieties marked by differences in the size and color of the tubers and in their habits of growth, has been established by experiments of recent years in our own country by the developing of a pea-sized tuber to one of a pound in weight in seven summers. The existence of sub-varieties will be learned by growing wild tubers from California, Texas, Arizona, Mexico, Peru and Chili, as has already been done in this vicinity by Mr. Burnet Landreth. It was discovered that the plants were generally white blossomed; some were dark green; others light green; some quite prostrate in growth, and others more erect; and what is quite important, that the Colorado beetle would not eat them. The tubers were yellow-fleshed, white-fleshed, oval, round and obovate.

The Peruvian Potato was first discovered in a growing state by the Spanish invaders of Peru, who saw it under cultivation in the vicinity of Quito. Peru, at that time, had an ocean frontage of about 2,500 miles, and included Ecuador, Peru as it is now, and a large part of Chili. The government was a theocracy and the people were devoted to agriculture; bringing water by aqueducts where required, using irrigation and fertilizing with guano, which then covered the coast islands until they were white and mound shaped. The birds producing this fertilizer came at certain seasons by the million and were protected by the government. Never, perhaps, was the terrace system of mountain agriculture brought to a greater degree of perfection or more extensively used by any people; and the sides of the Cordilleras were zoned with vegetation, varying in character according to the climate given by different degrees of elevation above the sea level. On these leveled

terraces the Peruvians cultivated at different heights the fruits of the tropics, the Indian Corn and the "Papas," or Potato. How long the Papas had been redeemed from its wild state it is impossible now to determine; but it will answer our purpose to know that the tuber grows abundantly over a long range of the Pacific slope, and that it can be acclimated and perfected by a few years of cultivation. The character of the wild Peruvian Potato was tested in 1828 by a party of officers attached to the United States frigate "Brandywine," as recently related to me by Dr. W. S. W. Ruschenberger, U. S. N. The vessel was lying in the Port of Callao, and the party visited the island of San Lorenzo, about a mile and a half from the town, climbed its declivity to an elevation of about 1,200 feet, dug up a quantity of wild potatoes, carried them aboard ship and had them cooked. They were found bitter to the taste and much inferior to the tubers perfected by cultivation. These wild potatoes were larger than those usually found in North America, which are rarely beyond the size of marbles. They were from two to two and a quarter inches long, of a flattened ovoid form and indented with eyes. San Lorenzo is a barren island about seven miles long and three-fourths of a mile wide, and rises to an elevation of about 1,400 feet. The Potato plants were dwarfed resemblances of their cultivated and improved descendants. Would it not be well to obtain and grow some of the potatoes of this island for hybridization with our more delicate varieties?

The Peruvian Potato was first carried from its native soil to Spain by Hieronymus Cardan. Pedro de Cieca, of Leon, published at Antwerp in 1554 an account of his seventeen years of life and adventures in Peru, in which he states that the Potato was at that time grown in Italy. Carolus Clusius, of Aras, a physician and botanist, wrote in 1583 that the Potato was then extensively cultivated in Italy. The tuber was therefore under cultivation in southern Europe long before it reached England from Virginia, and was grown in Spain as early as the year 1550.

Early navigators found the Potato under cultivation by the Indians of Virginia, by whom it was called the "Openawk;" this was, no doubt, a North American variety disseminated by the Indian tribe. Mr. Thomas Hariot, a member of the colony sent out by Sir Walter Raleigh to Virginia in 1585, is credited with having taken the first potato over to England in 1586, in a vessel commanded by Sir Richard Grenville. Mr. Hariot was a man of education, and devoted his attention to making discoveries and observations regarding the country, its commodities, and the nature and manners of its inhabitants, which he described in a book published in 1588. The potatoes he took over were given to Sir Walter Raleigh, who had them planted in his estate near Cork, Ireland, probably in 1587. The Potato was not cultivated in the United States by foreign settlers directly from Virginia tubers, but from Irish and Spanish stock, produced respectively from Virginian and Peruvian Potatoes. A colony of Scotch-Irish who settled in Londonderry, New Hampshire, in 1719, brought over and planted the former, and the latter were introduced at a later period, under the name of "Bilboas." These were larger, and were known in Pennsylvania as "Spanish Potatoes"; they had a pungent taste and odor, and neither variety was at all popular. The Irish stock was a small, bright yellow kidney tuber, a decided improvement upon the wild variety, but less so than the best potato of to-day is an improvement upon it.

The botanical name of the Potato plant was first given it in 1596 by Professor Caspar Bauhin, in his "Prodromos Theatri Botanici," in which he called it the "*Solanum tuberosum esculentum*." In England it bore the title of the "Virginian or American Potato." The first picture of the plant appeared in the "Herbal" of John Gerarde, surgeon, in 1597, under the title of "*Papus orbiculatus*." Gerarde had a large botanic garden in Holborn, London, one of the first of the kind in Europe, in which he grew both white and sweet Potatoes. The latter appear also in his "Herbal" as the "*Sisarum Peruvianum*, or *Batata Hispanorum*."

White potatoes were of slow introduction in the United States, partly from their taste, but more from an idea among working people that they were a slow poison, and that their daily use would prove fatal to the consumer in about five years. This erroneous notion was prevalent for a number of years, until it was finally broken up by the example of educated and wiser people. Had the potato of a hundred and fifty years ago been as inviting to the palate as is that of to-day, the poison idea would have had but little weight. There is a curious inconsistency in the human race with regard to the fear of poisonous articles. The potato, the tomato and the egg plant were all, in their early days, suspected of being poisonous, and this groundless idea was enough to keep many people

from eating them; but why did not the same persons take alarm at the poison of whisky, tobacco, opium and other liquids and solids not necessary to health and unquestionably containing a poisonous excitant? At the very period when the prejudice against the potato was the most active in this city, the Grand Jury reported that the places where intoxicating drinks were sold were nearly equal to one-tenth of the houses in the town. The craving for excipients knows no fear of consequences; while, at the same time, the desire for food is discriminating and suspicious.—*From a paper read before the Pennsylvania Horticultural Society, by Robert P. Harris, M.D.*

Plant Note.

Cattleya Skinneri.

THE illustration on page 201 represents a large specimen of this beautiful *Cattleya*, from a photograph taken in its native country by the collector, when more than 800 flowers were fully expanded, with a number of buds to open. Owing to its enormous size, it was with considerable difficulty brought to the place where the picture was taken, and a number of flowers were unavoidably sacrificed. The plant was afterward packed and shipped to Europe, and perhaps it still occupies a place in one of the Orchid collections on the continent. A still larger plant of this species was imported by Mr. Sander some years ago from South America, where it had been grown in a tree near the dwelling-house of a laborer. This giant Orchid, which was figured in the *Gardeners' Chronicle* for March 8th, was so large that a special house was built for its reception. In its native country the finest and most vigorous plants are found upon rocks, in positions where very little moisture stands about them, and the blossoms are then much brighter in color and of greater substance than when the plants grow upon trees and are partly shaded. There is very little variation found in this species, the rarest form being pure white; and this form is hardly ever found in a wild state; the plants that are now under cultivation in our collections are nearly, if not all, obtained from the roofs of native huts and from gardens in Costa Rica, where they are grown exclusively for the flowers, used to adorn the churches during the "Semana Santa," or Easter week. Like the majority of *Cattleyas*, this species delights in an abundance of air while growing, and if placed in baskets so that the compost may be fully exposed to the air and be in no danger of becoming sour or stagnant, it will grow vigorously. This compost should consist of good fibrous peat with a small portion of sphagnum.

Foreign Correspondence.

Berlin Letter.

AT the last meeting of the Society for the Advancement of Horticulture the exhibition of forced Roses attracted much attention. These were grown from cuttings made late in March last year. Plants of La France and Marie Baumann about two feet in height bore from twenty to thirty-six buds and flowers of extraordinary health and vigor and of greater solidity than is usually seen in grafted plants. These cuttings were from forced plants, and, as soon as rooted, they were planted out in the open air in April in a bed thoroughly enriched with well rotted manure and deeply spaded. During the summer frequent applications of liquid manure were given. In November they were potted and brought into a cold house, where they remained until February, when the forcing began. It is well to note that no pruning was done; not a twig that was grown during the summer had been removed. The bushes had a diameter of from two to two and a half feet, and the leaves and flowers were of the best quality.

Another feature of interest in this exhibition were the hybrids of *Saxifraga Stracheyi* and its allies, with pure white, rose colored and red flowers, those of one plant closely resembling Peach-blossoms, not only in size but in form and color. The plants had been placed in a rather dark position, in order to elongate the peduncles, which are normally short.

On page 90 of this volume of GARDEN AND FOREST I stated that plants of *Chamaerops excelsa* were to be left out all winter in order to test their hardiness, and the result has been that they have passed through in good health. Perhaps, therefore, these Palms deserve the distinction of having survived a European winter in the open air in a higher latitude than any others. It is true that the last winter was mild, the lowest temperature being eight degrees Fahrenheit, and yet the fact is of the highest interest and invites farther experiment. To make such

experiments most valuable it would be necessary to test Palms which have been grown from seed from the most northern limits or from the highest elevation where the species is ever found.

The temperature in March was extremely high—eighteen degrees of Fahrenheit above the normal. One day the normal temperature of June 15th was attained, and, as a consequence of the excessive warmth, spring flowers were so ambitious and the development of the leaves of trees and shrubs so rapid that spring here resembled those of the high north. One was greatly reminded of the season at St. Petersburg, where the spring runs its entire course in a few days.

Amongst the shrubs the white and fragrant flowers of *Lonicera fragrantissima* are already open in the botanical garden, and near it are seen the rose colored flowers of *L. Standishii*. Near these two plants stands the lovely *L. Alberti* from Turkistan. When I ran over not long ago the species of *Lonicera* in the Royal Herbarium I discovered that this Honeysuckle had before been collected by Schlagintweit in the Himalaya, in whose herbarium it is preserved without a name,

the nurserymen yielded the points in dispute. There are in and near Berlin some 500 nurserymen, who employ some 2,000 gardeners.

I should be greatly obliged if some of your western readers would collect for me some seeds of *Erigonums*. These plants are well suited for culture here, especially on rockeries, but they are found in few European gardens. Their inflorescences are of the highest morphological interest, and I should like to study their development, but to do it I need the living plants.

Berlin.

Cultural Department.

Hardy Rhododendrons.

IT has been suggested that the experience of an old grower and lover of Rhododendrons might prove of interest and possibly help to promote the cultivation of these beautiful shrubs, and I therefore send a few notes of a general character, based upon many years of labor and careful observation.

It must be admitted that the cultivation of the Rhododendron

Fig. 35.—*Cattleya Skinneri*.—See page 200.

and now Dr. Koehne, who is elaborating a revision of *Loniceras*, finds that *L. Alberti* of Regel is a long known plant, *L. spinosa*, Jacq. *Corylopsis spicata*, S. & F., allied to the Witch Hazel, is another plant now flowering in the botanical garden, and very beautiful it is and well worth growing in any park or garden. Forsythias have become most popular here of late years, and there is hardly a cottage-garden in which there is not at least one of these shrubs covered now with its bright yellow flowers. It is specially adapted to our climate.

The strike of the under-gardeners was begun on the 1st of April, although it had been in preparation since last autumn. At that time the gardeners demanded of the nurserymen a change in their working hours, which was refused. This spring they sent a demand to the nurserymen that their working time in vegetable and plant nurseries should be eleven hours, while in tree nurseries and out-door garden work it should be ten hours, and that their minimum pay should be \$6 a month with board and lodging, or \$4.28 a week without board. Most of the nurserymen declared that those demands were not exorbitant, and yet they refused to subscribe to the terms, so the strike began. It seems, however, that at the last hour

in this country has made comparatively slow progress, in spite of liberal prizes offered by our horticultural societies and the high appreciation in which the plant is held in England, where it is a prominent feature in the decoration of all the fine places and where those grand exhibitions under canvas excite so much interest and admiration every year. The explanation of this indifference is found to some extent in a general impression, in New England especially, that our winters are too severe, or that the Rhododendron is so difficult of cultivation that only a few can succeed with it, and then only at the cost of much labor and money. That there is some foundation for this belief cannot be denied, and it is true that the mild and moist atmosphere of England is better adapted to its special requirements than the extreme cold winters and the hot, dry summers of this country. It is true also that many of the very finest varieties can be grown there which are tender here. But, on the other hand, it is equally true that a sufficient number of very attractive hardy kinds remain to satisfy the most ambitious horticulturist, and these, under favorable circumstances, can be grown here without much more care than is given to ordinary garden shrubs.

It should be more generally known that the list of well tested hardy kinds has been largely increased of late years, thanks to some of the skillful hybridizers in England, who have raised new varieties for this country with special reference to their hardiness combined with splendid foliage and the most gorgeous flowers. Enterprising nurserymen on this side of the water have also accomplished much in this direction, and it is to be hoped they will be repaid for their trouble and expense. To show what progress has been made in the introduction of new and choice varieties, I can testify that it is not a great many years ago when but very few of the bright flowering varieties termed precariously hardy were to be seen here; and I remember hearing the statement made by one of our most intelligent horticulturists that not one of them could be considered perfectly reliable in our most severe New England winters. All doubt, however, on this point has been entirely removed at the present day, for we have numerous fine crimsons and scarlets, many of which have proved as hardy and reliable as the old favorite *Everestianum*.

In the cultivation of *Rhododendrons*, a mistake is frequently made in selecting for them the most sheltered southern exposure that can be found and one where the sun shines on them the whole day, under the impression that they are all extremely tender. In such a location the soil is likely to become very dry and parched in midsummer, and the result is that the plants suffer from drought, which, together with poor cultivation, in my judgment causes more injury than our most severe winters. As is well known, the *Rhododendron* requires a cool and moist soil, and it is sure to suffer the moment the roots become dry, though the injury may not be apparent to the casual observer at the moment. The latter part of the winter, however, tells the tale in the browned foliage and then the injury is often wrongly attributed to the cold weather. The bad effect of drought is also occasionally seen in the spring in dead flower buds which have never fully ripened. For many years I thought extreme cold weather was the cause, but with closer investigation I have concluded it is oftener owing to very dry weather, and I am confirmed in the opinion by the fact that this rarely occurs except after an unusually dry summer. This objection, however, of selecting a southern exposure for planting will not apply with the same force in cases where the place is a reclaimed meadow or has a soil which keeps moist even in very hot weather; but these are conditions not very often met with; and I would recommend as far as practicable that plantations be made on the northern slope of hills, or where they will be shaded during some portion of the day by belts of trees or buildings.

After what has been said in regard to the great importance of moisture in the cultivation of *Rhododendrons*, it follows as a matter of course that a careful and thorough preparation of the soil in making borders for plantations is a necessity. Two or three feet of loam may answer for ordinary shrubs, but twice that depth is better for *Rhododendrons*, especially when they attain considerable size. It is now generally understood that peat is not indispensable, still it is highly beneficial, and I would confidently advise its liberal use when easily obtained, as well as a good supply of leaf mould, which I believe to be equally desirable.

The hybrids of *R. Catawbiense*, which are the most hardy in constitution, and from which by crossing the finest crimson and scarlet varieties are produced, have been sent out from England during the last dozen or fifteen years in large quantities, and varying as they all do in respect to hardiness, it has been no easy matter to ascertain with certainty which could be depended upon in our severe and changeable climate. An inspection of the foliage is generally a very sure guide, but it is not conclusive, and many cases of so doubtful a character occur that it is necessary, before a positive decision is reached, that they should be left out for several winters in order to settle this question satisfactorily. There are, however, many of these new and charming varieties which have been so thoroughly tested that they can be confidently recommended for general cultivation in this part of the country. One of these which is a favorite with many is *Lady Armstrong*, a pale rose, spotted and showy, with good habit and foliage. Others are *Scipio*, *Giganteum* and *Sherwoodianum*—all rose colored—and *Charles Bagley*, cherry red, with extra fine foliage. Among the crimsons we have quite a number which are great acquisitions to the hardy list and must soon find their way into all collections. *Mrs. Milner*, a rich crimson, I have had out many years. *Kettledrum* has proved very satisfactory, and so has *E. S. Rand*, which has been somewhat lost sight of. *H. W. Sargent* is a grand crimson, with an immense truss, but it has proved a little disappointing in habit. *Guido*, crimson; *James Bateman*; *Lady Clermont*, rosy scarlet and very desirable;

Caractacus, a rich purple-crimson, and *Old Port*, plum color, are all good. *Alexander Dancer* can be strongly recommended as of good habit and foliage, with a grand truss of bright rose flowers. *Minnie*, bluish white, spotted with chocolate; *Charles Dickens*, very hardy, dark scarlet; *John Waterer*, a free blooming dark crimson; *Mrs. Thomas Wain*, pale rose, and *Maximum Wellesianum*, blush, changing to white, with fine foliage, can also be safely recommended.

I now come to some of the still more recent and choice English varieties, which for several years I treated as half-hardy, moving them into pits in the autumn, where they remained during the winter. This mode of treatment not proving an entire success, I have been testing many of them by leaving them out in the borders all winter, some for several years and others only during the past two years, with very encouraging results, though it will be remembered that both summers and winters of the past two years have been exceptionally favorable for *Rhododendrons*. Still the thermometer at Wellesley has been down to five degrees below zero once, and twice to zero this last winter. They are magnificent plants with flowers of great beauty, and my experience with them, though limited to a few years, has been so very promising that I think they can be recommended to any one disposed to give a little extra attention to favorite plants.

J. Marshall Brooks is a rich scarlet, with a bronze spot, distinct and beautiful; *J. McIntosh*, a rosy scarlet; *F. D. Godman*, crimson, fine foliage; *Ralph Saunders*, purplish crimson, large truss; *Rosabel*, pale rose; *Lady Grey Egerton*, silvery blush, splendid truss and foliage. *C. S. Sargent* is one of the finest crimsons, and with its *Catawbiense* foliage will doubtless stand any old-fashioned New England winter. The Queen has a fine shaped flower, blush changing to white. *Mrs. Arthur Hunnewell* is pink with primrose centre, very showy and promising. *Mrs. John Clutten* comes with the recommendation of being the best hardy white *Rhododendron* in cultivation; I have at times felt discouraged in regard to its success in this part of the country, but with some coaxing have finally succeeded in raising some fine, good sized plants. Other noteworthy varieties are *Joseph Whitworth*, dark purple lake, large blooms, beautiful foliage; *Duchess of Edinburgh*, crimson, with light centre; *Duchess of Sutherland*, white, with margin of rosy lilac; *Duchess of Bedford*, crimson, light centre; *Marchioness of Lansdowne*, pale rose, with intense black spot, very showy; *Charles Napier*, clear rose; *Mrs. Shuttleworth*, scarlet, much spotted, and a very free bloomer; *Sigismund Rucker*, magenta; *William Austin*, bright crimson, abundant bloomer; *Meteor*, fiery crimson; *Sir Arthur Guinness*, fine clear rose; *Bacchus*, crimson, large truss; *Ne Plus Ultra*, finely shaded lilac-purple, good foliage.

Here is a list of over twenty very beautiful varieties supposed by me for many years to be tender in this vicinity, but I now believe a large portion of them certainly will be found hardy and great acquisitions to any collection. They, however, must be well cared for, and if water is not abundant and easily applied, they must be thoroughly mulched with some suitable material, or they will surely suffer from our hot and dry summers. I use for this purpose large quantities of forest-leaves, which are effectual, and when decayed make excellent nutriment for the plants. The objection that they are not very neat is easily met by a good covering of Pine needles.

I will here add to what has already been said on the importance of selecting a location where the plants will be shaded from the mid-day sun, that it is a precaution particularly desirable with these very choice and distinct varieties for the reason that if the weather happens to be very hot at the moment they come into bloom, the length of time the brilliant flowers remain in perfection is shortened very materially.

Notes from the Harvard Botanic Garden.

FRANCISEA EXIMIA AND *F. LATIFOLIA*.—Both these fine old Brazilian plants are now flowering freely in a stove temperature. The former is an evergreen shrub of bushy habit, with lanceolate leaves, dark green on the upper surface and paler underneath. The salver-shaped flowers are borne upon the tips of the young shoots, and measure almost two and a half inches across. They are of a rich purple color, with a white eye when first expanded, but afterward shade off to a beautiful lilac tint. It is certainly a handsome and most desirable plant when in full bloom. Specimens that are satisfactory as to form may be potted immediately after flowering, but those of ungainly appearance had better be pruned into shape and allowed time to break slightly first. Sharp sand, leaf-mould, peat and loam, in equal parts, the two latter being

fibrous and lumpy, will form the most satisfactory soil. They should be placed in a moist atmosphere after potting, and where a minimum temperature of sixty degrees is maintained. Syringe regularly, shade from prolonged bright sunshine, and water carefully until new growth appears freely. Water in abundance will be required during the period of growth, and the plants should then be placed as close to the glass as may be convenient. When the young shoots attain a length of about three inches pinch out the extreme tips, but do not continue this process beyond the latter part of September; and a month later remove the plants to quarters that are drier and from ten to fifteen degrees cooler. Full exposure to sunshine will now be beneficial; less water will suffice, though the roots should never be subjected to extreme dryness, and, as the flowers appear, syringing may be discontinued. Firm cuttings of the young wood, taken with a heel of an older branch, root freely in sandy soil, with strong bottom heat, moist atmosphere and shade. In general outline and in the character of its cultural requirements *F. latifolia* closely resembles *F. eximia*. The leaves, however, are obovate, while the smaller flowers are deliciously fragrant, and of a distinct blue

position), and the others diminish in size as they approach its extremity. The plant is tolerably tenacious of life, but special attention to its cultural requirements will be amply repaid. Repotting as soon after the flowering season as possible and abundance of heat and moisture, with shade from bright sunshine during the growing season, are the principal matters to receive attention. It thrives admirably in a mixture composed of two parts each of turfy loam and fibrous peat to one each of sand, leaf-mould and manure, the two latter being thoroughly decomposed. In the case of extra large specimens some rough charcoal may be added. A minimum temperature of sixty-five degrees should be maintained during the season of growth, and afterward gradually lowered about ten degrees. Plants that are continually kept in a high temperature flower about three months in advance of those that have been subjected to less heat after the growth has been completed; but their inflorescence is usually inferior, and eventually the plants become exhausted. It is due to the pressing demands on space in a botanic garden that the only specimen here is kept in a growing temperature throughout the year, and generally blooms early in March; under more rational

A Road in Sherwood Forest.—See page 197.

shade, with a prominent white eye, when they open, but in process of time the entire flower becomes pure white. It is a common thing to see at the same time blue, lilac and white flowers on one branch of the same plant.

MEDINILLA MAGNIFICA.—It would be difficult to find a more truly magnificent object than a well grown specimen of this plant in full bloom, and, being an evergreen, the massive foliage renders it strikingly ornamental at all seasons. It is a branching shrub of somewhat scandent habit, and attains a height of five or six feet. The stems, when young, are flattened, green and smooth, but become gradually cylindrical, rough and brown; and they are well furnished with leathery, obovate, glossy green leaves from twelve to fourteen inches long and about six inches broad. The whorled terminal panicles of bright pink flowers average about twelve inches in length, and they assume a drooping position which adds materially to their pleasing effect. Showy bracts of a delicate pink color, disposed in opposite pairs or whorls of four, also contribute largely to their beauty. The largest of these bracts—they often exceed five inches in length by four inches across—are at the top of the inflorescence (when it is in a drooping

treatment the flowering season would extend from the beginning of April till the latter end of May. It is, however, very accommodating in this matter, for by the steady maintenance of a maximum temperature of sixty degrees, after the growing period, the bloom may be retarded to almost any season of the year. It will thus be seen that a growing temperature is, in this instance, as requisite to the development of flowers as it is to the production of new branches; and, seeing that new growth makes its appearance soon after the flowers are shed, this is just what might be expected. It can be propagated by cuttings prepared from the growing points of young shoots.

SPARMANNIA AFRICANA.—This handsome evergreen shrub is a native of the Cape of Good Hope, and attains a height of ten or twelve feet under cultivation. It is of branching habit, and the branches are furnished with cordate-acuminate, dentate, light green leaves, which measure from four to five inches in length, and from three to four inches in width. Sometimes the leaves are lobed toward the apex. The pretty white flowers are freely borne in umbels, on the young branches, during spring. The numerous stamens,

with red filaments and yellow anthers, form a showy mass in the centre of each flower, and a series of barren yellow filaments, arranged round the fertile stamens, also adds to their good appearance. The branches and leaves and exterior surface of the sepals are clothed with downy hairs. *S. Africana* gives perfect satisfaction in an ordinary greenhouse, the temperature of which never falls below thirty-five degrees. Full exposure to light is at all times requisite, and a free circulation of fresh air on favorable occasions is beneficial. Specimens of all sizes will derive considerable advantage from being plunged to the rim in the open garden during the summer months, and when dry weather prevails a syringing toward evening will add to their healthful appearance. Plants should be potted early in spring. The tips of the young shoots root readily in a propagating frame at a temperature of about sixty degrees.

SOLANUM JASMINOIDES.—From a floricultural point of view this is perhaps the most useful and beautiful species of the genus to which it belongs. It is a native of South American countries, but succeeds satisfactorily in a green-house, the temperature of which never falls below forty degrees. Being of a climbing habit, it is seen to the greatest advantage when treated as a vine, and trained to walls, pillars or rafters. The younger branches then hang downward gracefully, and during winter and spring bear numerous racemose clusters of pretty white jasmine-like flowers, that are further adorned by conspicuous bunches of yellow stamens. It is a deciduous plant, the ovate-acuminate—sometimes cleft—leaves falling late in summer or early in autumn, and it grows most luxuriantly when planted in a prepared bed or border. When in active growth it requires plenty of water, but the quantity should be restricted during the season of rest, which continues from six to eight weeks after the leaves have dropped. The tips of firm young shoots make good cuttings, which root quickly in sand with the assistance of a little bottom-heat.

Wild Flowers under Cultivation.

EXPERIMENTS in the cultivation of wild plants often give results at once surprising and gratifying. The common Loosestrife (*Steironema ciliatum*), for example, is a plant which in its wild state attracts but little attention, and which but few persons will even recognize. A year or two ago I lifted a clod of its roots and gave it a position in my garden on the north side of a picket-fence and in the partial shade of a tree. The last summer it formed a charming mass of neat, clean foliage, borne on many erect, wiry, symmetrically branching stems three or four feet high, a cord tied to the fence affording a slight support, and when studded over with its airy, delicate, golden-hued blossoms, but few plants in my garden excited more interest or were more admired. It is, too, a lasting bloomer, and retains the freshness of its verdure until cut down by the frost.

Another plant that has especially pleased me under domestication is *Spiraea Aruncus*, or Goat's Beard. A clump among the shrubs in my garden is a most effective feature, making a luxuriant growth of a peculiarly picturesque habit, and the flower panicles produced are of immense proportions, the whole plant having improved wonderfully with the slight care it has received. During the early period of their growth, or until they are a foot high or more, specimens may be readily removed from their native haunts to the garden, and, in a rich soil, will thrive from the start. Care must be taken to discriminate between the male and female plants, only the former producing the large, showy flower-panicles. During the period mentioned I have never failed to separate the sexes by the marked reddish tinge of the stem and leaves of the female plants—a point which seems to me an interesting and noteworthy distinction. The foliage, however, of the female plant is more lasting, retaining its freshness until the seeds ripen, while in the male plant it begins to fade or dies soon after the flowers wither.

The Blue Wild Indigo (*Baptisia australis*), ornamental in flower and foliage, is an abundant strong-growing species along the shore of the Ohio River within my field of observation. A few years ago I transferred a specimen, with its remarkably deep set, strong and bulky roots, to my grounds, setting it in an open situation in a compact sandy soil. It flowered and did well the first season, but the next year or two it was less thrifty and failed wholly to bloom. One autumn I loosened the earth about its roots to the depth of eight or ten inches and covered it with two or three inches of well rotted manure. In the early spring I again loosened the soil and at times gave it a thorough soaking, letting it take in as much as a painfull. That season it made a remarkably vigorous growth,

and produced a number of strong racemes of beautiful flowers. These plants, in their natural state, grow in an alluvial or sandy soil, and are often submerged by a full river for days together, which also serves as a strong fertilizer. To attain the highest success in their cultivation I am persuaded these conditions must be largely imitated.

Every one is familiar with Jack-in-the-Pulpit, or the Indian Turnip, but there are but few, it is safe to say, who have any knowledge of its congener, the Green Dragon (*Arisæma dracontium*), a scarcely less interesting plant, less common, perhaps, and less conspicuous as it grows naturally, but by no means rare. It could well lay claim to the distinction of bearing one of the oddest or most grotesquely formed leaves (it has but one) among native American plants. A little imagination might see in it a dragon's foot and claws. Whether it was this that suggested it or the fiercely acrid juice of its root-stock, and that of its kind, the name given to the plant is singularly appropriate. A bulb or corm set in my garden half a dozen years ago grows uniformly a much larger leaf than I have ever seen it in its wild state, measuring last summer a little over a foot across, and with seventeen leaflets, instead of "seven to eleven," as given by the botanists. With its very odd leaf and remarkably long and slender orange colored spadix it well deserves a place in the wild garden as a curiosity. Its scarlet fruit cluster is no less brilliant than that of the Indian Turnip.

Another domesticated wild plant in my garden worthy to be mentioned here is the Goat's Rue (*Sephrosia Virginiana*). It is enough to say of it that it retains under its new conditions all of its natural attractions of showy flowers and pleasing foliage. Some have told me they have failed in their attempts to grow it. In its natural state here it grows its long slender roots in a dry slaty soil in a more or less sunny exposure. I have conformed somewhat to these conditions. These are a few of the experiments of a busy man who loves flowers with a few plants growing wild in this region. They are presented with the hope that others may be induced to make similar trials and share with him much pleasure and instruction.

Hardy Plants for Cut Flowers.—I.

FLOWERS for home decoration are now in universal demand, and this is one of the uses to which hardy perennial plants are specially adapted, because their requirements are few and they can be successfully cultivated by any one who can command a plot of ground. Of the thousands of perennial plants in cultivation, many whose flowers are beautiful, fragrant and durable when cut can be found adapted to any American garden, whatever may be its situation. It is now established beyond question that a selection of plants for the open border can be made to yield flowers in variety and profusion for nine months in the year, or from March until December.

Among the earliest of hardy subjects, the bulbous section take first rank. Such harbingers of spring as Squills, Chionodoxas and Crocus cannot be considered useful for cutting and it is on the numerous family of Narcissus that we most rely for the first really useful cut flowers. When Easter occurs well on in the season, as in the past two years, Narcissuses are always plentiful in the open air with us and can be relied upon for an abundance of flowers when they have become well established, which is usually the second year after planting. The varieties of Narcissus are numerous and naturally perplexing to the beginner, who is chiefly interested to know which are a few of the best kinds that will produce the longest succession of bloom. Out of a large collection, Golden Spur, one of the newer kinds, is always the first to bloom, followed a day or two later by *N. princeps*, a noble kind, and then comes Sir Watkin, the Giant Welsh Chalice-flower "with foliage like leeks," as Mr. Burbidge once observed when showing me his fine collection in Trinity College Gardens, Dublin. *N. bicolor Horsfieldi* then follows, and is at once the most distinct and beautiful variety in cultivation. The Jonquils should be added for their fragrance, and lastly, the beautiful Poet's Narcissus and its varieties. Thus it will be seen that some half dozen kinds, lasting over as many weeks, are to be relied on as perfectly hardy and vigorous, and are sufficient to form the nucleus of a collection that may be added to as opportunity occurs. It should be remarked that Narcissuses succeed well in shady places under trees, and may be used with charming effect for naturalizing among grass, many an English meadow being at the present time literally a garden of Daffodils. American cultivators need not trouble themselves about the necessity of lifting the bulbs annually after they have flowered, although this is practiced and preached

by some of the best English growers. We have always found that the greater extremes of drought and solar heat experienced here at the resting period of the bulbs will be found sufficient for ripening them, and that lifting them, besides the labor incurred, only produces artificial conditions which are unnecessary and too often detrimental.

Passaic, N. J.

E. O. Orpet.

Endive.

THIS is an excellent winter salad, resembling the Dandelion in habit of growth, and quickly grown from seed, which should be planted about June 15th, and for a succession at intervals until August 1st. Hot weather is unfavorable for bleaching the plant, and cool nights and days up to November are most favorable. The Green Curled gives the best satisfaction. The Moss Curled is too tender; the Batavian too coarse. Plant either in rows to be thinned, or in a bed for transplanting. It bears transplanting well, but will grow where sown if plants are thinned to one foot apart each way. It is a great feeder, and well repays good care. When about ten inches across the leaves should be gathered about the centre in an upright position and tied with cotton cord wound three or four times about the plant.

There are other methods of bleaching, but none so quick, sure and satisfactory as tying the plants as recommended here, and I have discarded all others. The bleaching is completed in ten days or three weeks, as the weather is warm or cold. The plants should then be lifted with a ball of earth and brought into a light, cold cellar in fall, and set on the bottom in sand, where they can be kept until New Year's or until wanted for use. The white, crisp, slightly brittle leaves are pleasant to the eye and the palate.

Endive is a plant for the home garden, where it can be grown as a second crop when transplanted after Peas, Beans or other early vegetables. It should have sunlight for good development, as it makes a small and infirm growth in shade.

West Springfield, Mass.

W. H. Bull.

Where to Plant Tender Trees.—A beautiful and thrifty Deodar Cedar, growing on a rocky, elevated site, suggests the thought that many partly tender trees might be grown if planted in situations where strong or late growth would not be made. The tree above referred to has made little growth each year, but this was sturdy and well ripened. It did not appear to have suffered at all in any of the severe winters through which it has passed. Many trees of doubtful hardiness would thrive under the same treatment. A few years ago I saw a fine specimen of *Magnolia grandiflora* growing on the hills of Roxborough, the coldest and highest part of Philadelphia. There was no protection save that of a dwelling, which was on the north side of it. It is well known that Peach and Apricot-trees growing in hilly places are rarely killed back in winter, as many are in rich, low ground.

Germantown, Pa.

Joseph Meehan.

Hybrid Perpetual Roses.—If I were asked to name twenty of the best hardy Roses for out-door planting my list would be the following: Jean Liabaud, Paul Neyron, Mrs. John Laing, Ella Gordon, General Jacqueminot, General Washington, Alfred Colomb, Comte de Paris, Beauty of Waltham, Gloire de Margottin, John Hopper, Madame Charles Wood, Marie Baumann, Madame Masson, Madame Joseph Desbois, Queen of Autumn, Ulrich Brunner, Jules Margottin, Lady Helen Stuart and Eugene Furst.

These are all plants of strong constitution and produce magnificent blooms. The collection contains all the range of colors found in the Hybrid Perpetual class, from the light flesh tint of Madame Joseph Desbois to the velvety crimson of Jean Liabaud.

Richmond, Ind.

E. G. Hill.

Triteleia uniflora.—This charming little bulbous plant is a native of Buenos Ayres, but it is quite hardy in the New England States, where its pretty star-like flowers are freely produced late in spring. They are borne singly on slender stalks, well above the somewhat drooping linear-acuminate leaves, which measure about one-eighth of an inch in width and from five to seven inches in length. The flowers are about an inch in diameter and of a delicate lilac color when they expand, fading with age to pure white on the upper surface. For a cool house it is a very effective pot plant during winter and early spring, and with a little extra care it may be induced to flower from the latter part of fall onward. In pot culture about a dozen bulbs should be planted—in a six-inch pot, using rich sandy soil—in September, and placed in a shaded and unheated frame, where, with attention to watering,

the free admission of air on favorable days and protection from severe frost, they may remain until about two weeks before they are wanted to bloom. On removal to a sunny greenhouse, which affords sufficient artificial heat to exclude frost, the flowers will speedily develop. By attention to the offsets, which are freely produced every year, the stock of bulbs may be rapidly increased. They should be planted in the garden and allowed to attain full size before being used for pot culture.

The Forests of North America.—II.

Die Waldungen von Nordamerika, ihre Holzarten, deren Anbaufähigkeit und forstlicher Werth für Europa im Allgemeinen und Deutschland insbesondere. Von Dr. Heinrich Mayr. M. Rieger, München, 1890 (New York, Steiger & Co., 25 Park Place).

It is in the description of individual species and their products that Dr. Mayr's learning and conscientiousness most strikingly appear. For instance, his words about the Douglas Spruce (*Pseudotsuga taxifolia*), just now the most interesting of our trees to foreign foresters, fill more than twenty pages. Its aspect as a feature in our western forests and the methods employed in cutting it and transporting the wood are described in the chapter devoted to these forests. Then, in the section where each species is separately taken up, he describes its botanical characteristics and mode of development; its behavior under different conditions of climate, exposure and soil is carefully noted and illustrated by comparative tables of figures; the anatomical characteristics of the wood are exhaustively discussed and tables are given comparing it with the wood of the European Fir, Spruce and Larch; and its parasitical enemies and their action are considered, the adaptability of the tree to German forest-needs being of course borne in mind throughout. And then, in the chapter where the fitness of our trees to European conditions is especially discussed, he comes back again to the Douglasia (as it is called in Germany), and defines the stations which should suit it best and the value it will probably have. "It is to be expected," he says, "that the Douglasia, in so far as the excellence of its wood is concerned, will become the 'Larch of the level and low lands.'" When its wood is richest in substance and heaviest, it comes near to that of the European Larch; when it is lightest it stands on an equality with the best and heaviest Fir, Spruce and Pine-wood. "As the value of wood for fuel and to a certain degree its strength run parallel with its specific weight, the wood of the Douglasia may be called superior to that of our native conifers (the Larch excepted) in these qualities." Specific weight, he adds, is less decisive with regard to durability, but from the other factors which indicate this quality he concludes that "in this respect likewise the Douglas Spruce stands on an equality with the Larch." It is interesting to note that on comparing the wood of this tree as supplied by a specimen grown near Hanburg, in Germany, which was cut in 1882 at the age of fifty-two years, having remained remarkably low in a fully exposed situation, with the wood of a three-hundred-year-old specimen from Oregon, he found the former heavier and firmer in substance. The very best European stations for the tree he decides to be the north-west coast of France, and then Belgium, Holland and southern England, while neighboring districts, like Ireland, Scotland, and those portions of Germany which are directly influenced by the North Sea and the western Baltic, should prove almost as good, and its range may be extended, as far as climate is concerned, throughout the whole of Germany except its highest mountain regions. But he is careful to note that for each given district seeds should be imported from the proper American region, those trees grown from seed collected in Montana being proof against frost but slow-growing, while those from Oregon and Washington are quick-growing, but susceptible to spring and autumn frosts. Seeds from Colorado, he adds, which are recommended by dealers as giving frost-proof trees for our Eastern States, are not adapted to German use. "The plants are hardy, it is true, but very slow-growing indeed."

Dr. Mayr is careful to point out that the question whether an exotic tree can be grown in a given part of Europe is by no means the same as the question whether it will there serve the purpose of the economic planter. It does not fall within his province to discuss the value of such trees for park or street planting, or as objects of beauty or interest in ornamental grounds. He concentrates his attention upon their ascertained or possible serviceableness in the economic forest,

where, of course, they will be expected not merely to exist or to become objects of beauty, but to support forest-conditions, to grow at least as rapidly as indigenous species, and to produce wood which is at least equal to that which these species supply. Of course, the subject is a complicated one, and with most of our trees much actual experimenting must still be done before their worth to European foresters can be estimated. But whatever can be done by theorizing, based on a wide and careful observation of facts in this country and a thorough acquaintance with European conditions, seems to have been done in this volume. The danger of generalizing from too brief experiments is made clear, and is emphasized by reference to many European species which, for a time, seem to do thoroughly well in America, but before they reach maturity fail and die. The same thing, says Dr. Mayr, may be expected in many cases in Europe—a quicker growth to begin with than is shown by related native trees and then a sudden and hopeless failure. The reasons for this phenomenon are of course referred to, but at a length too great to permit quotation now. It is especially interesting to follow the author through the chapters where he discusses the different elements which are comprised under the general term location. Relative degrees of cold constitute of course only one element, and the significance of this one is modified by the character of the others, as by the greater dryness or moisture of the atmosphere or of the soil, or a greater or smaller degree of evaporation in the plants themselves as affected by particular situations. "Nine-tenths," Dr. Mayr explains, "of all cases in which injury through frost in winter is affirmed, belong in the category of injury from drought, the consequence of a hindered or diminished water-supply brought about by frost. In this way, perhaps, may be explained the apparent paradox that many species which are known as 'hardy' in a notoriously cold climate pass for 'tender' in a notoriously mild one. Probably the plants stood in the first locality in a moister atmosphere or were better protected against evaporation, while the susceptible plants in the warmer locality had to fight against dryness and frost. It is to be expected that all species which come from the warm coast-zone, delight in swampy stations and live associated in large forest-masses will be particularly susceptible to a combination of frost and dryness. At the head of the North American species which come thus in question stand the conifers of the Pacific Coast west of the Cascade Mountains. In order to cultivate these in Europe without loss through frost it seems as though only the coasts, the interior of large forests, damp river and mountain valleys, or even a damper subsoil than they require at home, will be found available. The Lawson's Cypress, the Douglas Spruce, the Giant Hemlock, the Sitka Spruce and the Nutka Cypress are entirely hardy under these conditions; but if they are lacking, then even the Sitka Spruce fails, which, in its own home, on the shore of Alaska, stretches almost to the glaciers. Each plant, indeed, possesses a certain adaptability to changed conditions with regard to moisture, which may be increased or diminished by the dampness of the air and by the dampness of the soil, each by itself or both working together. The plant reacts notably against this combination in varying ways. Researches upon this point are not known to me. It is true that I now lack the literature to search with regard to it, and the contributions which I shall bring to the support of the statement rest, therefore, on my few personal observations. But if a literature on this subject does indeed exist, it cannot be very large, for the moisture of the air as a weighty factor in plant life has as yet not been sufficiently recognized." We cannot follow Dr. Mayr into the analysis which he then gives; but it seems worth while to call attention to the words last quoted as indicating a profitable field for other students.

Interesting, too, are his notes on the dangers which American trees will probably run in Europe from animal and vegetable enemies. He doubts whether they will be freer from such dangers than native plants. Indeed, he notes a number of probable special sources of danger, from the love of men to break off vital bits of new and interesting specimens, to the delight which, for some unexplained reason, all animals seem to find in exotic kinds of food. Again, epidemic diseases are more apt to afflict trees when many of a given kind are massed together (as is usual in economic planting) than when they are mixed with other species in the primeval forest.

But it would be an almost endless task to pick out all the most interesting and instructive passages in this book. We do not profess even to have called attention to some of those which, above all others, merited notice. To accomplish this one would have to read the volume more than once, and carefully weigh the relative significance of all its parts. Desiring to bring it as quickly as possible to the notice of our readers,

we have simply chosen passages here and there for their illustrative value as showing the field it covers. Meanwhile we must conclude with a brief mention of the scheme for the use of our trees in Germany, which is outlined in Section XI.

Repeated stress is laid on the fact that little can be settled with regard to the economic value of our trees until they are tested in the forest itself, where, naturally, they often do better than in isolation. Dr. Mayr recommends, therefore, that small colonies of a given species shall be formed in forests which already exist, and all due measures taken for their protection and for observing their development. Then he mentions many American trees which are well worth using or testing, explaining his special reasons in each case. And then he fixes the limits of five distinct zones into which German lands may be divided according to general climatic conditions, and gives from one to three lists of plants for each of them. The first list contains those trees which have already been thoroughly tested, the economic value of which is established, and which therefore should be added to the small list of species now used by the forester, and planted in large masses. In the second list he places trees which are evidently valuable, which give good promise of adaptability to German conditions, and which it is, therefore, worth while to test in an extensive way; and the third indicates less valuable species which likewise have not yet been thoroughly tested. For example, the first zone he defines includes "the warmest, lowest regions of Germany, the valleys of the Rhine, the lower Main and the Neckar, with a medium yearly temperature above nine degrees Centigrade and a medium temperature during the period of most rapid growth of over seventeen degrees, where the Oaks do best, the Chestnut regularly ripens its fruit, and the cultivation of the Vine, of Tobacco and of Maize is possible." For this region he indicates, in Class I., the Black Walnut, the Shell-bark, the Pig-nut and the Mockernut Hickories, and the Sugar Maple; in Class II., the Black and the Yellow Birch, the Red Cedar, Lawson's Cypress and the Douglas Spruce; and in Class III., the Black Cherry, the Catalpa, the Occidental Plane, the American Elm, the Locust, and three Poplars, *P. balsamifera*, *P. monilifera* and *P. trichocarpa*. It may be noted that as a shrub which may cover the forest-soil and yield a valuable by-product in its fruit, Dr. Mayr recommends *Vaccinium macrocarpum*, from its fitness for ground upon which wood-production, even if possible, is, at all events, of minor importance.

Correspondence.

Botanical Names.

To the Editor of GARDEN AND FOREST:

Sir.—I often hear the remark: "If it were not for the hard names of the plants, how I would like to study botany, but I know I never could remember them." This too prevalent idea with the young is largely due to the "wits" who hold up botany and kindred sciences to ridicule by selecting some of the most difficult and uncouth names and making them the text for so-called humorous paragraphs in the daily papers. These articles are funny, no doubt, or they would scarcely find a place in our great dailies, and yet the more witty their railery the more damaging the influence.

But occasionally we see an article, apparently written in all seriousness, to deplore the use of scientific names. As a case in point, I quote from a newspaper article: "True, my reading is mostly in history and literature, but that is not because of my indifference to science, which I regard as the highest of all truth, but because of the horrible jargon in which science is concealed rather than revealed. A rose by any other name may smell as sweet, but it does not sound as well when called an *Anastatica hierochuntina*. . . . I went to a flower show a short time since and saw the common Smilax labeled *Myrsiphyllum asparagoides*, and a Primrose marked *Primula Sinensis fimbriata*, and I thought of Wordsworth's

'A Primrose by the river's brim,
A Primrose only was to him,'

and how his soul would have expanded if he had only known that other name. Now I confess this is all Greek to me, and I want to know if it is a help or a hindrance to the acquisition of knowledge. To myself I feel that it has been a hindrance, and it seems like a relic of the middle ages, when all important works were written in Latin for the benefit of the few who were Latin scholars."

It is not the science itself to which the correspondent objects, but the hard names which have deterred him from study. But really the names are not as formidable as represented. They help instead of hinder the study of science.

True, the botanical names are in Latin or have Latin terminations, this being the common language of all natural science the world over, so that a plant may be known by the same name in every tongue. If each nation had a nomenclature of its own, and a poor little plant had as many names as there are languages in the world, then there might be some reason in scolding about the nomenclature. The case is worse than this with common names, however, for each language has several of them for the same plant and many of these are misleading.

The correspondent cites for an example of a hard name *Anastatica hierochuntina*. The common name of this plant is "Rose of Jericho," which has misled him into thinking it a Rose or something like one. Now a little knowledge of botanical nomenclature would have shown him that this plant was a long way from the Rose family, and he would have known that the common name of all true Roses is Rosa. It certainly is more simple, more systematic, more easy to remember, if a single name—like Rosa—is used for all plants in one genus, with distinguishing specific additions for the separate species, than it is to have a name for each species which gives no hint of a plant's relationship to other plants. The name of the genus is like the family name or surname of an individual—as Davis or Smith—and the name of the species corresponds to the Christian name—as John or Jane. If one wished to study the ethnology of any race, would he consider it necessary to learn the names of the individuals before he learned the characteristics of the nation? Or would he make a plea that the names were so hard that it prevented him from gaining a knowledge of the people?

Any person who has a natural love of plants can become familiar with the botany of his neighborhood in one season. If not more than a hundred plants were well examined it would give a good general idea of our flowering plants, or if a person will patiently study even twenty well chosen examples he will thereafter have no difficulty in determining the species around him. The system of botany is so perfect that the study of one plant gives us a knowledge of the whole order or family to which it belongs.

Now if we look more closely at the dreadful botanical names, we find that when the genus was known to the Greeks and Romans, the old classical name is commonly retained. For instance, the genus Aster (of which we have so many wild species in the United States) is from the Greek word meaning a star. These little Star-flowers are everywhere on our roadsides, and in the woods and swamps, lighting up and making our waste places gay with their pretty white, or blue, or purple, or pink starry flowers. The specific name of these various Asters is often given to denote some character of the plant, so that the name is a clue to the species. Thus *Aster grandiflorus* means one with flowers large and showy; *A. acuminatus*, one with leaves oblong and sharp-pointed; *A. longifolius*, one with leaves long and linear. Would a common name for each species of Aster be an improvement upon this?

Some difficult names have been given to plants in honor of individuals; for instance, *Eschscholtzia Californica*, named for the discoverer, Eschscholtz, who found it in California, as the specific name indicates. Kosteletzkya, named for the Bohemian botanist, Kosteletsky, is another hard one; but these names are more difficult to write than to pronounce. Hundreds of other persons to whom genera and species have been dedicated have not been so unfortunate in their names, as, for example, the botanist Magnol, whose name lives forever in the beautiful genus Magnolia. Claytonia is named for Clayton, an early botanist in Virginia; and Jeffersonia for the President who sent the first exploring expedition over the Rocky Mountains. Other genera are named from some property of the plant, or appearance of the leaves or flowers or stem. For example, the genus Hepatica is named from the shape of the leaf, which resembles that of the liver; Sanguinaria from the blood-like color of the juice of the plant. The specific name, when it does not indicate where the plant comes from—like Japonica, from Japan—is most generally truly descriptive of some characteristic of the plant.

All this elementary talk is of course for beginners, and it means that while scientific nomenclature might be greatly improved, really it is much better, simpler and easier to learn than the wits would have young people and ignorant people believe. It will be found, too, that scientific nomenclature is necessary even as a basis of common names, and gives the only key to the identification of plants by common names. And last of all, it will be found that good botanists—those familiar with scientific names—know the most about the common names.

Vineland, N. J.

Mary Treat.

Destruction of Wild Plants by Roadsides.

To the Editor of GARDEN AND FOREST:

Sir.—A spasmodic attack of clearing up roadsides to which rural districts are frequently subject, has of late swept away several of those groups of Nature's planting upon which the eye lingers restfully when they are permitted to remain along county roads. One of these, where the pedestrian could pause among the shadows and note the variety of foliage, must have dated back many years, for its principal feature was a self-planted Apple-tree, the branches of which reached across the fence and drooped to meet a fringe of Hazel-bushes bordering the outer side of the footpath. Other shrubs gathered about these, one an Elder of large proportions, and a beautiful object when covered with its creamy white flowers or dark purple fruit. Many vines added their grace in fitting places, making altogether a pretty arbor, beneath which Ferns and Podophyllum found needed shade. All this and much more might have been urged in favor of this mass of growth, while on the other hand complaint was made, not without cause, that it was cumbering the pathway to the annoyance of passers-by. A judicious trimming, however, of the under branches and a removal annually of dead Blackberry-canes, would have obviated all difficulty in walking and saved it from wholesale destruction. Now the offending side of the tree having been cut away, and the shrubs trimmed off or grubbed out, there is little left above ground that bears promise of verdure in the near future; not at least until Nature shall have recovered her wounds and restored the loss from mutilation. Neither is there cause for hope that the tender plants now hidden beneath the soil will long survive unsheltered the extreme droughts to which the summers here are subject.

Another place of unusual interest to a lover of Nature was a small piece of marsh-land noted for the variety and brilliancy of its wild flowers, the great number of birds that dwelt among the Sedges and Willows, and also as the only spot in the neighborhood where *Cypripedium spectabile* might be found.

The land thus occupied, being destined to serve agricultural uses, is to be drained, and the occupant's first step was to burn it over, after which grub-hoe and axe were plied at the root of every tree and shrub. A strip of young timber on the higher land next the road, though of little use when cut, even for fuel, but of great value for shade and an attraction to birds, was included in the general uprooting, and many a choice wild flower will die out, lacking the protection and nourishment its leaves afforded.

It is to be regretted that persons who have highways in charge do not recognize the advantages to be derived from verdure in place of parched and barren roadsides.

The dry seasons and sweeping winds are a menace to the farmer, which he is constantly deploring, yet few land-owners spare any standing trees or protect those that spring up in waste places.

Klinger Lake, Mich.

Dorcas E. Collins.

Fuchsia triphylla.

To the Editor of GARDEN AND FOREST:

Sir.—In a late number of GARDEN AND FOREST, in a paragraph referring to Fuchsias, I find the statement made by a writer in the *Revue de l'Horticulture Belge* that *Fuchsia triphylla*, a native of San Domingo, was rediscovered in 1884.

Permit me to say, as a matter of historical accuracy, that it was rediscovered on that island by myself in the early spring of 1873. I disposed of it to Mr. Isaac Buchanan in the autumn of the same year, and later on he disposed of it to another florist, who in turn disposed of it (as I am informed) to one of the large florists in the neighborhood of London.

New York.

Thos. Hogg.

Notes.

Miss A. M. Vail, of this city, has been elected associate editor of the *Bulletin* of the Torrey Botanical Club.

The *Pacific Rural Press*, in its issue of the 12th of April, has an admirable portrait of the late Dr. C. C. Parry.

The perennial Candytuft is a plant which should be in every spring garden. Its leaves keep green all winter and it is already covered with snow-white flowers which endure for several weeks.

At a late meeting of the Royal Agricultural Society at Georgetown, Demerara, Mr. Rodway explained how ripe bananas could be dried so that they would keep in a condition of freshness long enough to be carried to England or America. The fruit was said to retain its flavor unimpaired for a long time.

The death is announced at Lucerne, in his seventieth year, of M. D. Bulan, one of the most successful and most generally employed landscape gardeners of France in recent times. His principal work was the Park of the Tête d'Or at Lyons, where he changed a great unhealthy marsh into one of the finest pleasure grounds of Europe.

The Massachusetts Horticultural Society has obtained the consent of the Boston city authorities to erect on the Common a mammoth tent for a horticultural exhibition to be held during the sessions of the Society of American Florists at their annual meeting in August next. It is expected that the exhibition will be one of notable interest.

A correspondent of the *Tribune* from Lakewood, New Jersey, states that more than 200 packages of *Epigæa* and *Pyxidanthera* are sent every day from that station by express and mail to distant friends by the sojourners there. Hundreds of the guests at the hotels, it is asserted, make it their daily labor to gather these beautiful little plants. There seems to be an unlimited supply of both species, but they will be practically exterminated from this region if this thoughtless devastation is carried on a few years longer.

In the "Sixth Annual Report of the Commissioners of the State Reservation at Niagara" the account of their work is carried down to the end of September, 1889. The number of visitors to the Falls is estimated at half a million annually, as many as 5,000 coming sometimes during a single day. The building of good roads in certain parts of the Reservation is the chief improvement now proposed. A map of the Reservation and its neighborhood is given with the report, and a geological appendix prepared by Mr. G. K. Gilbert, which tells the history of the Niagara River.

In our own country neighborhoods an effort might well be made to follow an example set in France, as recently noted in the *American Agriculturist*. In many French communes boards are set up bearing the following instructions: "Hedgehog: Lives upon mice, snails and wire-worms, animals injurious to agriculture. Don't kill a hedgehog. Toad: Helps agriculture; destroys twenty to thirty insects hourly. Don't kill a toad. Cockchafer and its larvæ: Deadly enemies to farmers; lays 70 to 100 eggs. Kill the cockchafer. Birds: Each department of France loses yearly many millions of francs through the injury done by insects. Don't kill the birds."

Two weeks ago we published an article by Mr. T. L. Mead, explaining how the various Palms in his collection at Oviedo, Florida, had endured the freezing weather of early March. Mr. Mead adds the following note in reference to the Ferns which were then growing in the open air: Older plants of *Cibotium Barometz* and *Blechnum Brasiliense* and young ones of *Lomaria ciliata* lost all their leaves, but new fronds are already beginning to push. The Maiden-hair Ferns, *Adiantum cuneatum* and *A. Wiegandii*, were hardly touched, and a quite extensive assortment of greenhouse Ferns bordering a small pool of water suffered less than many native species, *Osmundas*, etc., growing close by them.

Last year the Maple was chosen as the "State-tree" of New York by a vote of those participating in Arbor Day exercises, and it is suggested that this year a "State-flower" shall be selected in the same way. The student in the common schools of this state who presents the best essay, not exceeding 400 words in length, on the most profitable manner of observing Arbor Day, will receive a gold medal given by Mr. William A. Wadsworth, of Geneseo; and prizes of \$100 and \$50 will be awarded for the best kept district-school grounds in the state. Superintendent Draper announces, furthermore, that due mention in his report for 1891 will be made of the common-school student who, before the first of October next, shall transmit to his office the best collection of bark, wood sections, leaves and fruit of the "State-tree."

The comparative test between the heating power of steam and hot water, which was carried on a year ago at the Massachusetts Agricultural College, and which was reported in this Journal at the time (vol. ii, p. 186), has been repeated this year, and according to the last bulletin from that experiment station, with similar results. The record for the hot water boiler was in brief as follows: Total coal consumed from December 1st, 1889, to March 18th, 1890, 6,598 pounds; average daily temperature for the time, 49.74 degrees. The record of the steam boiler was: Total coal consumed from December 1st, 1889, to March 18th, 1890, 9,784 pounds; average daily temperature for the time, 48.39 degrees. That is, the steam

boiler, with nearly fifty per cent. more coal, gave an average temperature more than a degree lower for three months and a half.

Two gentlemen, one of whom is Senator Evarts, recently joined in building a charming stone bridge for the benefit of their fellow-citizens in Cornish, New Hampshire. "Such an act," says the Boston *Herald* very justly, "is not a great affair, but it is one of the many ways in which our New England towns may be put on a par with the villages in old England, where the bridges, built across the different streams, are often the most picturesque attractions in the landscape, and give it a distinction that could be gained in no other way. Next to a good road in a country village is the finely arched stone bridge that spans some tiny stream, and wherever you find the good road and the picturesque bridge people of refinement and education are apt to locate their homes. Though a small thing in itself, it may be believed that no single investment can be made in many of our New England villages to yield richer returns than the tasteful bridges which are constructed over its waterways. Here is an unoccupied field where men of wealth can show their taste and give distinction to their native towns, and be sure to have their names handed down to posterity in grateful remembrance."

Experiments conducted by Professor Goff at the Wisconsin Station last year indicate that a solution of carbonate of copper is a certain remedy for the Apple-scab. The solution is composed of one ounce of carbonate of copper dissolved in one quart of aqua-ammonia (strength twenty-two Baume), diluted with 100 quarts of water. One and a half gallons of the diluted solution are sufficient to thoroughly spray a tree of medium size, and two gallons for one of large size. It follows, therefore, that four ounces of carbonate of copper and one gallon of ammonia will make 100 gallons of the diluted solution, which is sufficient to spray fifty large or about seventy-five medium trees once. The ammonia should be kept tightly corked with a rubber stopper. To this the precipitated carbonate of copper should be added at the rate of one ounce to one quart of ammonia, in which it dissolves, forming a very clear, deep blue liquid. When ready to commence the application, add this solution to the water used for spraying at the rate of one quart to twenty-five gallons of water. The bottle containing the solution should be kept tightly corked. Three or four applications are advised, and it is probable that one made just after the leaves expand and before the flowers have opened would add to the efficiency of the treatment, as the fungus commences its growth quite early in the season. The liquid is applied with a force pump fitted with some kind of a spraying nozzle.

A correspondent of *The Garden* writes that the wild garden at Kew is just now very attractive with bulbs of various kinds in full flower and apparently quite at home amongst the long coarse grass. One slope is a sheet of gold with the Dutch Crocus. Besides the yellow variety, there are large purple and white forms and a host of rare species which seem to grow perfectly here. The Glory of the Snow (*Chionodoxa Luciliae*) has also made a home here, and from its scattered condition the bulbs seem to have produced seed freely. Should this prove correct we have here a splendid subject for naturalizing in the uncultivated portions of our gardens. It is perfectly hardy, taking good care of itself, and is withal one of the most beautiful of our early spring flowers. Near by are the Squills, *S. Siberica* and *S. bifolia*. Narcissi are also here by the hundred thousand, and we are told. The higher parts of the mound are at present white with *N. pulchellus praecox*, and should it become established here, which seems likely, so far as one can judge, it will be beautiful in the years to come. On the lower ground *Triteleia uniflora* is coming up strongly, and so are Primroses of all kinds, and on the sunny side are innumerable Tulips, Hyacinths, *Anemone fulgens*, Hepaticas and various Daffodils, prominent amongst them being the double *Telamonius*, which has already formed quite a sea of glaucous green foliage. Nearly all these bulbs would be equally at home in our own gardens and they all bloom at a season when flowers are especially charming.

Catalogues Received.

P. H. FOSTER, Babylon, Long Island, N. Y.; Deciduous Trees Evergreens, Roses, etc.—H. B. MAY, Dyson's Lane Nurseries, Upper Edmonton, England; Ferns and Fine Foliage Plants.—LEWIS ROESCH, Fredonia, N. Y.; Grape Vines, Small Fruit Plants, etc.—T. C. THURLOW, Cherry Hill Nursery, West Newbury, Mass.; Deciduous Trees, Evergreens, Fruit Trees, etc.—J. H. TRYON, Willoughby, O.; Grapes.

Legislation for the Adirondacks.

THE Legislature of this state, which is soon to adjourn, has enacted three or four laws which ought to prove of distinct and permanent advantage to the Adirondack forests, and it has failed to pass certain other laws which are imperatively demanded if the safety of the forests is to be assured. Railroads are most to be dreaded as agents of swift and certain devastation. Every new line which penetrates the woods means remediless ruin as far as it goes, and the first duty of the law-making power toward the forest is to prevent the laying of another foot of track on the State Reservation. Existing charters cannot be revoked, but the authority now resting with the Commissioners of the Land Office to grant to railroad companies land belonging to the people of the state should be restricted; and the failure of the bill exempting from this provision of the General Railroad Act the lands included in the Forest Preserve is a calamity.

On the other hand, convictions for trespass on the state lands have been made more practicable by the Change of Venue Act, which authorizes a trial where it may be possible to secure jurors who have not been educated in the belief that the state has no right to protect its own forest-property. The amendment now pending, with good prospect of passage, in regard to the cancellation of sales by reason of occupancy, which shifts the duty of giving notice from the state to the claimant, will be of great assistance in quieting the title to lands which of right vests in the state. The act appropriating \$25,000 for the purchase of lands by the state is important as establishing a policy. The amount named will buy but little land, but it recognizes the principle that absolute ownership on the part of the state gives the only assurance of a proper administration of the forest-region. But perhaps the most important step taken was the enactment of the concurrent resolution directing the Forest Commission to investigate the advisability of establishing a State Park to contain some three million acres, embracing the head waters of all the streams

of consequence which take their rise in the wilderness. The report which is to be made to the next Legislature is to include an estimate of the probable cost of the land, with suggestions as to the proper boundaries of the park and a discussion as to its various local features, with reference to their value for this special use.

Of course this does not commit the state to the policy of buying the lands now in private hands which it will be necessary to acquire if a compact area of the size contemplated is secured. But it does show a readiness to consider the question with a full appreciation of the fact that to carry out the project will cost millions of dollars. Many of the questions to be answered are puzzling enough. If the scheme is considered advisable, will it be more prudent for the state to go into the market as a buyer or to condemn the land and trust a commission to fix its value? Will it be better to insist on taking all the land as it is, or to pay a lower price for some and allow the removal of its marketable Spruce, say, under certain restrictions? Scores of questions like these will obtrude themselves upon the Commissioners, and even if they could command the help of skilled subordinates in making the needed surveys and investigations they will be obliged to keep steadily at work throughout the year if a report is prepared which treats the matters involved with adequate thoroughness.

Our own belief is that the land should be bought, and that it never can be bought to so good advantage as it can to-day. The difficulties in the way of the purchase are almost appalling, but they will grow more serious every year. The entire tract could have been bought for a song when the Commission with Horatio Seymour at its head reported on its condition, and every one now sees that it would have been a wise investment for the state. If the proposed purchase is now abandoned there is little doubt that the people of the state in after years will look back to this failure as another lost opportunity.

THE following paragraph appeared last week in the *Boston Herald*.

Monday afternoon, Thomas Coughlin, living on the Tower road, Lincoln, started a brush fire near his place, and, the wind shifting, his barn was destroyed with its contents, entailing a loss of \$1,500. The fire continued through the woods, and yesterday afternoon reached the dwelling of Michael Leahy, on the same road, destroying it; loss, \$4,000. Last evening the fire was still raging furiously, and the residents of the town had turned out en masse to fight the flames, which have burned over nearly 300 acres.

Similar paragraphs appear almost daily at this season of the year in the daily journals published in the Northern States.

A man thoughtlessly and carelessly sets fire to his brush-heap. He may or may not have selected a proper day for this operation. The wind changes or increases, and before he knows it, almost, his bonfire has extended to a neighboring bit of woodland, and once having started, the conditions at this season of the year being particularly favorable for the spread of fires in the woods, a great conflagration is generally the result. It is folly to expect people to improve their woodlands or to hold forest-property as long as such property is subjected to unrestrained burning at the hands of irresponsible people. The lumbermen's adage that "no forest is safe until it is cut down" will hold until the public is willing to afford some protection to property of this character. It is not easy to see why one man should be allowed to jeopardize his neighbor's property and another should be restrained from doing so. This community would not hold that a resident of Fifth Avenue who should be restrained from building a big bonfire on a windy day in his back yard would suffer injustice, and yet his fire would not be a greater menace to his neighbors' property than the fire of a farmer burning his brush-pile. There can be no security of forest property in the Eastern and Northern States until laws are passed regulating within proper limits the setting of brush fires by individuals on.

their own land,' and making them responsible for the damage caused by such fires. To secure the passage and enforcement of such laws, should be the aim of our various forest associations and of all persons interested in forest-property.

THE Autocrat of the Breakfast-table has the love and veneration of the old school New Englander for those noble Elm-trees which, when he was a boy more often than now, were the glory of the typical New England homestead; and thirty years and more ago he proposed the scheme of an imaginary work illustrated by photographs taken upon the same scale of magnitude, and accompanied by letter-press descriptive of New England Elms. Now at last this scheme assumes definite shape, and Little, Brown & Co., of Boston, are to publish "Typical Elms and Other Trees of Massachusetts." Dr. Holmes himself, as is fit and becoming, stands god-father to the enterprise in a charming introduction; the illustrations are reproductions, by the photogravure process, of photographs made by Mr. Henry Brooks, of Medford, whose fellow-townsmen, Mr. L. L. Dame, furnishes the accompanying text which supplies historical and statistical information about the different trees. Tree lovers in America have long felt the desirability of a work of this sort to preserve portraits of famous and remarkable American trees just as Strutt preserved in his classical "Silva Britannica" portraits of famous British trees, and Mr. Brooks earns their gratitude by doing this very thing. The work is not taken in hand too soon. Many of the trees which were famous in New England when New England was an English colony, disappeared long ago, as have many of the less famous trees Dr. Holmes speaks of in his preface; and the number of really great and distinguished trees is growing less every year in all the northern parts of the country, where changed conditions, material and social, are rather against their successors replacing them in historical interest or in mere bulk of trunk and spread of branches. Mr. Brooks' book will appeal to all lovers of trees. It will be a quarto volume of more than one hundred and twenty pages and will contain fifty illustrations. It proposes to show the possibilities attainable in Massachusetts by trees of different species under favorable conditions. Trees remarkable for age, beauty, size or historic interest have been selected.

Flower Painting.

TO paint a flower well four things must be shown: color, form, texture and substance; the hue of the blossom must be rendered, its outline and the shape of its petals, the peculiar quality of the surface of these, and the degree of solidity or fragility in which their accumulation results. Then, to make a good picture with the chosen flowers, other things must be considered—as the grouping of the subject, its lighting and the general color-scheme of which the hue of the flowers themselves forms but a part. The task, in short, is a very complicated one. If the amateur is apt to consider it the easiest he could attempt, his recklessness is explained by the fact that even a poor rendering of a very beautiful theme will attract the uncritical eye. One needs to paint admirably well to please any one with the picture of a potato; but a picture of a Rose, though it be but a travesty, passes for something pretty with the majority of observers.

The more experienced artist, knowing the difficulty of his enterprise, usually takes the quite allowable course of insisting more upon one side of his theme than upon the others. Perhaps he lays most emphasis upon the decorative effect of his picture as a whole, trying to do no more than indicate the characteristics of the flowers which are its most prominent feature. He arranges them in an effective mass and insists on their coloristic beauty as related to the surroundings which he has supplied for them, leaving their form, their texture and their substance to be divined from the hints he gives. If these hints are rightly given, if they point to the truth although they do not explain it, and if the main explanation is truthful and beautiful, the critic finds no fault with the picture. He accepts it as an interpretation of one quality which the flowers possess; and he knows that it is not needful that art should try to show more than one thing at once. Naturally, in this kind of flower painting, only such models should be

chosen as lend themselves best to the special aim in view. Peonies, Chrysanthemums, China Asters and a hundred common summer flowers like the Eupatoriums and Goldenrods are by nature adapted to a treatment in which a mass of gorgeous color is the aim, depending little upon form, texture or substance for the beauty we find in them; and the same may be said in a lesser degree of Geraniums and of double Violets, which are good material for smaller pictures of the kind. Any one who has been familiar with our annual exhibitions will remember the delightful large water-colors of Miss Greateorex, where, very often, masses of brilliant blossoms have been shown in the white paper cones dear to Parisian peddlers, giving a delightful picture not, in strict truth, of the flowers, but of their coloristic beauty.

It would not be wise to choose such flowers as these when effects of linear beauty are desired in a picture, but there are others admirably suited for such a purpose, like the Iris, the Amaryllis, the Narcissus, the Tigridia, and many kinds of Lilies, from the Japan Lily of the garden to the Wild Lily of the fields. All these are exquisite in color, but owe their peculiar charm even more to form. So beautiful, indeed, are their forms that if these are sympathetically felt and faithfully rendered, color may be entirely suppressed and still the picture be pleasing. A black and white drawing of a row of China Asters would be scarcely worth making; but such a drawing of a row of Irises might be well worth seeing. Decorative artists have known these facts in all the great building ages of the world. The Lotus, the Honeysuckle, the Iris, the single Rose and star-shaped blossoms of one sort or another have been most conspicuous in architectural ornament when it is painted as well as when it is carved.

Certain flowers are chiefly remarkable for what may be called dignity of bearing. The Gladiolus has this dignity together with great beauty of form in the individual flowers; the Fox-glove, the Larkspur, the Tuberose and the Crown Imperial have it; and the Hollyhock has it without any special elegance of form. Again, a graceful habit is the most characteristic trait, as with the Solomon's Seal, the Laburnum, many flowering shrubs, and, in a different way, the Lily-of-the-Valley and the Poppy. Still again, an angular, somewhat eccentric manner of growth is the plant's main characteristic, as in many which Japanese artists love to paint; and flowers of such kinds should, of course, be painted so as to bring out their special qualities most clearly.

No one would paint flowers chiefly for their texture (as one might paint a piece of satin) or chiefly for their substance; these are characteristics which can sometimes be almost overlooked, and at other times be made of accessory importance. That is to say, when the picture as such is the prime consideration, when a general decorative effect is desired above all else. When we come to absolute portraiture—to the rendering of flowers for themselves, not for the part they can play in some larger scheme of beauty—then texture and substance must be as much considered as form and color. To give the shape and tint of an Azalea blossom without giving its translucent texture, its fragile substance, would be to caricature it. To paint a Catherine Mermet Rose and not show that it is solid and heavy would be—not to paint this Rose. Naturally it is very difficult to achieve all these qualities together—to give the form of a flower exactly without making it seem hard, its color exactly without slurring its form, its substance exactly without travestying its texture. It is so difficult that we rarely see complete success except where the task has been simplified as much as possible. The best portraits of flowers are apt to be those where a very few blossoms of a single sort have been arranged and lighted as simply as possible. When Mr. La Farge shows us a single Water Lily he gives its form, its color, its texture, its substance—almost its odor. But did he conceive a large group of Water Lilies with adjuncts of various sorts, arranged and lighted so as to make a striking pictorial effect, he would probably choose some one quality of the flower for accentuation and merely hint at the others. At all events, though success with his single blossom cannot have been easy, it would be infinitely more difficult with many.

When flowers are painted as they grow out-doors in masses, forming part of a landscape composition, then, naturally, nothing but their color need be insisted upon, no matter what may be the dignity or elegance of their forms upon closer examination. Color is always the quality that, as painters say, "carries furthest," remaining distinct at a distance where forms and even habits of growth may be quite invisible.

On the average exhibition wall we seldom enough find any true excellence in the painting of flowers. Even good taste in the placing of the models so that their peculiar characteristics might best be presented to the painter is very rare. Gladioli are heaped together in a low bowl; double Violets are spread

out in a ragged line; Hollyhocks are plucked from their stems; Pansies are strung into a frieze; rough little Chrysanthemums are stuck up stiff and single. But Roses—it is Roses that are most often attempted and most seldom portrayed. Years ago we complained that they were always too hard; now things have changed—they are almost always too soft. Their color has been the sole concern. Achieve this, the painter seems to say, and what matter though they look as if made of a layer of cotton wool without thickness or outline or velvety surface? The worst is that even color cannot be achieved unless texture at least is given; we may match the tint of a Rose-petal in cotton wool, but the two tints will not be the same. When, from time to time, we find evidence of an eye that has seen the whole beauty of a flower and a hand that has had the skill to render it, then we are indeed content, though we see nothing more than one Rose on its stalk or two Carnations in a tiny bottle. We are content, although the portrait can hardly be called a picture, just as when, on the other hand, we find a beautiful picture we are content if it only indicates the beauty of the flowers that inspired the painter. To ask for everything together is to ask what only the greatest masters of the brush could give us. Indeed, it is doubtful whether any great master has ever given us, could even give us, a canvas in which we should have perfect pictorial beauty of an impressive kind, and perfect portraiture of flowers as well. Yet nothing is easier, thinks the amateur, than to paint flowers.

An Old New England Bridge.

THE bridge of which we give a picture on page 215 is on the old Boston and Newburyport Turnpike, and spans the Ipswich River at Topsfield, where for fifty years it has borne witness that such a structure can be at once rustic and monumental looking, that it can show the most evident solidity and yet harmonize perfectly with the natural aspect of the shores between which it stretches.

There is nothing about this bridge to show whether it stands in New England or in Old England, and it would look as thoroughly at home in any country where stone of a similar kind can be found. The semicircle is the simplest of all arched forms, and is certain to be selected by primitive or rustic builders; the comparatively shallow voussoirs, as small as is compatible with safety, are likewise characteristic of men whose desire is to build as cheaply as possible, and who think of security rather than monumental effect; and the irregular shape and rough surface of the other stones, and their association without mortar, tell a similar story. On a small scale it is the same sort of a wall that we find in the so-called "Cyclopean" structures of primitive Greece. And work of the same sort is still seen in the farm-walls of all parts of New England where there are granite ledges to be easily split. There is no reason why bridges of just this character could not be built everywhere in these districts to-day; and our picture is sufficient proof of the desirability of building them.

A dozen miles below Topsfield, at Ipswich, is the more famous "Choate bridge," which was built about 1760, and whose stone arches are still as sound, and a great deal more beautiful, than when they were first erected. The Black Willow, the White Maple, the Red Ash and the Swamp White Oak here fringe the banks of the Ipswich, and make them interesting, but the beauty of the river scenery is heightened by these solid spans of time-colored stone. And yet to erect them nothing was required but the unskilled labor of country masons, guided by the instinct of some one who knew the practical and artistic value of the simple round arch and the massive wall.

Our illustration is from a photograph by Rev. E. C. Bolles, D.D., of this city, to whom we are indebted for its use.

In a California Cañon.

ASPECTS of out-door life in California have often received literary treatment in the broad way, and on a large scale. Yosemite and Shasta are known, and the forests of giant Pine, close-carpeted with trailing Ceanothus, and the mountain acres brilliant with Calochortus blooms. But many a Californian can leave a thickly settled valley of orchards and find himself, in ten minutes' walk, in a flower-crowded mountain cañon, flooded with April sunlight, and stirred by all the springtide sounds and pulses. Perhaps Thoreau would have thought this as wonderful and satisfying as to dwell in the remote fastnesses of those Sierras that King, Whitney and Muir have so finely revealed.

The cañon I have just visited is one of the many small ones in the Coast Range on the eastern side of the Santa Clara

Valley, sloping west. The sea-winds rise and pass over them, and the fog drifts through the deeper river-cañons, so that these short, steep ravines are warm and sheltered, full of early pasturage and bloom. Their charm is in their nearness. A hundred yards from the wide wheat fields and the closely tended orchards of Apricots, Peach, Prune and Cherry, now in the full current of bloom, carries one into the mouth of the wooded cañon, which rises sharply, with little turns and pauses, to the outer crest of the Coast Range. If one goes quite to the top, it is only half a mile, and a broad rolling mesa with hill-tops rising over it extends several miles and then descends to another valley. The cañon consists of just this wooded, steep half mile of ravine, and its flower-covered sides sloping to the north and south. There are thousands of such cañons in California, and thousands that are much larger and more imposing, but not more interesting to the lover of hills and trees.

There were flowers in bloom all winter in the sunny shelters of this cañon, not many, to be sure, but a few flame-colored *Eschscholtzias*, the brilliant California Poppy and golden Mustard, and the wild Pea by the brook. A month ago, even this rainy and late season, the Larkspurs began to bloom on the yellow shale in sheltered spots. The grass has been growing everywhere since the first rains, and now, in these early days of April, it is knee-high in many places, and the heads of Wild Oats are half out of their sheathes. It is a tangle of growth from the mossy rocks by the water's edge to the windy summit of the hill.

The place is locally known as "Morrison Cañon," and the little stream is Morrison Brook. At every step on the way up its course, except when one is hidden under the great Oaks and Maples, the slightest backward glance reveals the sloping width of the orchard-planted valley, the Bay of San Francisco and the purple San Mateo Mountains beyond, filling up the whole western horizon.

First, at the foot of the hills, between the Almond-orchard and some one's vineyard sloping south, where the brook crosses the lane, bordered with Willows and Sycamores, one finds early blue and white *Nemophilas* in clusters in the grass, one or two plants in a place. There are brilliant masses of glowing *Eschscholtzias*, and above on the hill-side blue and purple Larkspurs (*Delphinium simplex*), and saucy *Dodecatheons*. The cañon begins, as most of them do, in well-pastured slopes, but the bottom is full of Live Oaks, just in bloom, Maples with leaves half grown, and Sycamores, Horse-chestnuts and Alders, all in the first rush of spring.

Pretty soon, as we go on, the hillsides are seen to be covered with patches of color, in acre-wide splashes. Here and there are Buttercups (*Ranunculus Californicus*), far more firm in texture than those of New England, and lasting a week or so in a flower-vase. There it is the pretty purplish blue *Gilia* (*G. multicaulis*), mingled with the white *G. dichotoma*, and Clovers, with half a dozen little *Cruciferae* and *Compositae* that make up in numbers for what they lack in individual glory. Clumps of the scarlet Painted Cups (*Castilleja foliosa*) illumine the hill-side. This fine perennial often has forty or fifty heads on a single plant, and blooms most of the year. It grows in clumps with the lovely red stemmed, "Rock-brake" Ferns (*Pellaea andromedaefolia*) that dot the warm hill-sides. Such clusters as they make, too, in this old-fashioned district, where even the children are careful not to destroy the roots! You gather all you care to carry from one or two clumps.

Since one has begun to seek the Ferns, a step below the path into the shelter of the trees and rocks reveals the Gold Fern (*Gymnogramme triangularis*), which children love to gather and press on cloth to leave the pollen-stamp of dusky yellow. Still further down the ravine at the bottom of the cañon the Gold Fern is more abundant, and with it, in moist, mossy crevices of rock, are young pink-tinted and emerald fronds of the delicate *Adiantum emarginatum*. On the northern slopes are tall Chain Ferns (*Woodwardias*) and taller bracken. There are white and purple Trilliums there, too, and spicy-scented Wild Currants (*Ribes tenuifolium*) just passing out of bloom, while higher up a mass of Holly-leaf Cherry (*Prunus ilicifolia*) is just beginning to flower. Somewhere about here there is a Cercis-tree that ought to be well in blossom, and the pretty Wild Gooseberries are abundant. *Ribes Menziesii* has a little whitish flower, and after a while a prickly, oval, red berry that children like. *Ribes divaricatum* has round, smooth, black berries, really excellent and worthy of cultivation.

On the hill-sides, close to the fragrant new-budded Oaks, are massive, semi-tropic plants of the *Balsamorhiza*, with its many-flowered yellow heads. Near them are groups of rose-

colored Wild Onions (*Allium unifolium*), and thousands of the blue-flowered Camass (*Camassia esculenta*), which once was one of the most common growths of the valley, eagerly dug up by grizzlies and by Indians. In the opens, near the trees, creeping along the ground or clambering over bushes, one finds the white Star-flowers and graceful leaves of the great Man-root (*Megarrhiza Californica*), whose large, prickly balls, filled with seeds and soapy pulp, are gathered by the country boys to throw at each other in imitation of snow-ball fights. Along in these opens, on the slope, one finds the purple and yellow *Fritillaria lanceolata* now, and more or less all summer. Vines of the common Clematis (*C. ligustricifolia*) cover some of the Oaks and Sycamores. The delicate white Star-flowers (*Tellima heterophylla*), one of the Saxifrages, grow in these fringes of the wooded part of the cañon.

Higher up the hill-slopes, but still not far away, are yellow, wild Violets (*Viola pedunculata*), with their brown backs and habit of clustering in colonies, a few yards across. This beautiful plant has been naturalized in some of the valley gardens, where the flowers are often as large as a quarter of a dollar. The sweep of grass over the rounded hill-top is cream-white for acres with the fragrant Cream-cups (*Platystemon Californicus*) and flame-red with Poppies. In places the Orthocarpuses, such as the purple and white *O. purpurescens*, mingle with white and blue Lupins, Gilias, Phacelias and the white and pale magenta Collinsias, to make a dazzling patchwork. Some of the most effective *Compositæ* of the Coast Range-region seem somewhat lacking in this particular cañon; but the rare flowers, becoming scarce elsewhere, are still massed almost as abundantly as twenty years ago. The broader slopes of the mountains show tints of white, yellow, scarlet, purple and blue from the valley below, and many species of plants contribute to the effect; but Buttercups, Eschscholtzias and Castillejas certainly cover the widest areas. It seems as if a thousand children might gather posies on the pastures that slope to this one cañon without lessening their brilliant colors.

Charles H. Shinn.

Vegetation in Southern Alabama.

LATE in February I wrote to GARDEN AND FOREST, giving some account of the vegetation here which showed that it was much farther advanced than was usual at that season of the year. Soon after—that is, in the early days of March—a norther swept over this region during the prevalence of which the mercury fell to twenty-four degrees, Fahr., and of course proved destructive to many tender plants. In observing the damage inflicted upon the various forms of plant-life in the garden, the field and the forest, it is interesting to note the variety in the injuries sustained by the plants which were overtaken by this cold blast when they were in their most active growth.

Of the ornamental trees and shrubs from the tropics and most of the plants from sub-tropical regions, considered hardy with us, all were more or less injured, but only a few were killed outright. Of the more tender kinds, the Cestruums, Brugmansias, some of the Lantanas, such as *L. Camara* and its varieties and most of the Abutilons were killed to the ground and entirely lost, as also were the Grand Duke and the Star Jessamines (*Fasminum Sambac*, var., and *F. pubescens*). The following had the younger branches killed and were stripped of leaves and flowers: *Rhynchospermum jasminoides*; the China-berry-tree (*Melia Azederach*); Crape Myrtle, *Lagerstræmia Indica*; Oleanders, the white being the greatest sufferer; *Hibiscus mutabilis*; *Plumbago Capensis*; Pomegranate; *Magnolia fuscata* and *Sterculia platanifolia*. Only the three last species are producing a new set of flower-buds.

Of the woody plants of the same category, the following escaped almost unhurt, receiving no check in the progress of their vegetation: *Pittosporum Tobira*, Azaleas, various Viburnums, at the time more or less with open flowers; *Laurus nobilis*, Cape Jessamine (*Gardenia floribunda*), the sweet-scented golden Jessamine (*Fasminum odoratissimum*), Hydrangeas and all of the Indian or Tea Roses, which had in some localities their flower-buds injured, but were soon producing again an abundance of flowers. *Cycas revoluta*, *Zamia integrifolia* and such exotic conifers as Biota, Retinospora, Cupressus, Araucaria, Cunninghamia, Podocarpus, were not in the least damaged. Of the bulbous plants, many of them far advanced, the true Lilies were cut down; Amaryllis, Gladiolus, Alstrœmerias, Zephyranthes were but slightly injured and are at present in full flower.

The greatest injury was inflicted upon fruit-trees. The branches of the Orange were killed to the larger limbs; the Japanese Medlar suffered severely—the young, tender wood

of the branches and the greater part of the foliage is dead. Covered with the blackened, shriveled fruit and the dead leaves, this tree presents a sorry sight. The Fig crop will prove a total loss, and that of the Pecan has been cut down to a very great extent; all the youngest shoots and the flowers and leaves, just emerging from the cover of their winter bud-scales, having been killed. The Japanese Persimmons or Kaki in my garden are killed to the root.

Strawberries received but a slight check, from which they soon recovered. Protected by a slight covering of straw, they continued to produce their fruit, and shipments to northern markets were but little interrupted. The damage to the products of the vegetable-garden and the truck-farm was not as great as was first anticipated, although the comparatively small proportion of the crop of Irish Potatoes already above ground is entirely lost, and so is the crop of Peas, from which shipments to northern markets had just begun.

The deciduous trees of the forest were stripped of their new foliage, and a fortnight after the frost they still presented the bald and sombre aspect of midwinter. Among the Oaks, the shoots of this season, with the flowers and foliage more or less advanced, were destroyed in the following species: Spanish Oak, Post Oak, Upland Willow Oak or Blue Jack, Turkey or Barren Oak (*Quercus Catesbaei*), Water Oak, Laurel Oak and Willow Oak (*Q. Phellos*). The Live Oak escaped all injury, and the various Hickories, with the exception of the Pecan, were found to have received no damage. The Cherokee Rose is covered anew with a second crop of flowers. The Pines and other coniferous trees of this section, which at the occurrence of the frost were either just past flowering or in full flower, do not seem to have sustained any injury.

New or Little Known Plants.

Ligustrum Sinense.

THE illustration on page 213 represents a branch of the Chinese Privet gathered last November in Parsons' Nursery, at Flushing, near this city, and serves to show the value of this plant for the autumn decoration of gardens. *Ligustrum Sinense*, although it is by no means a new plant, is not very often seen in gardens, and it gives us therefore a good deal of pleasure to find it flourishing in this climate. The number of plants which retain ornamental fruit on their branches until the beginning of winter is not large. Such plants, however, are very valuable in this climate and it is desirable therefore to add as many to the short list as possible.

This *Ligustrum*, as it appears at Flushing, is a loose-growing shrub, six or eight feet tall, with slender branches covered with light gray bark. It is no doubt an evergreen in a milder climate than this, or holds its leaves until spring, at least, as there was a large part of them on the Flushing plants at the time of our visit, and they were still bright and fresh.

The fruit is small, but of a beautiful dark color, and is produced in the greatest profusion on all the upper branchlets of the stems, which thus appear to end in great terminal racemes of berries, one or sometimes two feet long and a foot or more broad.

A flowering branch of this plant was figured in 1878 in the *Gardeners' Chronicle* (n. ser. x., 964); but it is the fruit and not the flowers which is its chief beauty and makes it a desirable plant to cultivate.

Foreign Correspondence.

Covent Garden, London.

COVENT GARDEN, or "Cummin Gardin" of the costermonger, and "Mud-salad Market" of *Punch*, is one of the sights of London which visitors are recommended by the guide-books not to miss, but which few ever see as it should be seen. Whilst the rest of London is sleeping, Covent Garden is all life and bustle, for the market begins at four A. M. All night long, carts, vans and wagons, piled with hampers, boxes, cabbages and garden-produce of all kinds, are rumbling along the many streets which converge at Covent Garden. They come from the suburbs of London, from the wharves and from the railway-stations bringing the produce, not only

of English gardens, but of Germany, France, Holland, Italy, Australia and America, for sale in this market. Thousands of tons of vegetables, fruit, plants and flowers are brought here, sorted, sold by auction or otherwise, and taken away again on almost every day in the year.

Covent Garden is within a stone's throw of the Strand, which runs equidistant between the market and the River Thames. It is not far from Westminster Abbey, of which it once formed part of the grounds, Covent being a corruption of convent. The Convent Garden, "an enclosure or pasture browsed by deep-udder'd kine, and probably the haunt of the lark and nightingale." In 1552 it was granted to John, Earl of Bedford, and in 1631 the market square was laid out, and the arcades or piazzas erected. The market was confined to a grove of trees, beneath which the stalls of the dealers were placed for shelter. By the middle of the eighteenth century the market had become important; but it was used for the sale of other com-

wide and fifty feet high. These again are flanked by the shops and offices of wholesale dealers and agents. Auction sales are held here daily at ten o'clock, and from soon after midnight crowds of porters are engaged in transferring from the vans outside packages of all kinds and from all directions. Huge cellars below all the buildings and passages afford storing accommodation for vegetables and fruit which are not for immediate sale. Hundreds of bunches of bananas and pineapples from the West Indies are stored here to ripen. Above the shops there are more storerooms. Four staircases lead from the central passage to a range of conservatories stocked with aquatic plants and animals, foreign birds of all kinds, hardy plants, principally conifers, in pots and tubs, with other garden material, all calculated to delight the dweller in town and tempt him to buy.

The roads surrounding the markets are broad, for the convenience of the large vans which in the morning block the

Fig. 36.—*Ligustrum Sinense*.—See page 212.

modities besides the products of the garden. In 1830 the numerous wooden sheds and stalls were swept away and replaced by the present market-house. Loudon wrote of this building in 1831: "To walk through this market with the recollection of what it was three years ago, gives rise to a variety of reflections. By what cause has it come to pass that the pillared grandeur and temple-like magnificence, which in former and no distant times were exclusively devoted to the edifices consecrated to the gods or occupied by princes, are now judged appropriate to the scene of humble industry and the abode of every-day people!"

The whole market occupies a space about 400 feet square, or, say, three acres. The buildings consist of a central avenue or arcade, with shops on each side, which are stocked at all times of the year with the choicest and richest fruits and flowers. These are open all day. Parallel with the arcade on each side is a spacious glass-roofed hall 200 feet long, sixty feet

way. The flower-market is a handsome structure, which was erected in 1885 to meet the enormous increase in the wholesale trade in this department. It covers an area of about 150 feet square and fifty feet high. A broad central path and numerous narrower side-paths divide the whole into plots, upon each of which is a cast-iron stage with three tiers, the top one eight feet from the ground. Upon these the plants and flowers are arranged. The space is let in lengths of ten feet, the name of each holder being over his stall. This space is rented at the rate of one shilling and threepence per square foot per annum. Even this market is not nearly sufficient to hold all that is brought by the London market-gardeners, for whose exclusive use it is kept, and outside there are numerous vans from which the flowers and plants are purchased direct. This is probably the handsomest and best arranged flower-market in Europe, and it is the depot of the very best of flowers and flowering plants that England can produce. Every

morning by four o'clock the stalls are crammed with the choicest of what is grown by the London market-gardeners, and by nine o'clock, or even before, it has all gone, and the market is closed.

The Duke of Bedford receives from rents and toll levied on all goods brought to the market something like £20,000 a year.

Covent Garden is the principal of the three markets in London where garden products are sold. A large proportion of the daily vegetable and flower requirements of the four million inhabitants of this great city is distributed from here. The wealthy proprietor of a West End flower-establishment, the humbler green-grocer and florist, the crafty costermonger and the poor flower girl all come here for their daily or weekly supplies. The streets are crammed with vehicles of all kinds either discharging or loading; gangs of men are rushing to and fro with loads of baskets or boxes, and for about five hours all is bustle and noise. Gradually the vehicles get away, the noise of the workers decreases, until by nine o'clock, or about the time when the comfortable Cockney comes down to breakfast, the market is over, and Covent Garden has assumed its daily quiet. Few who see it in the day have any idea that in the small hours of the morning this small corner of London was alive with busy men and women, and almost every foot of the square and adjoining streets was packed with loads of fresh vegetables and flowers "all a blowin' and a growin'."

Pruning the Peach.

THE fruit-buds of the Peach are this spring quite generally killed by frost. Opportunity is thus afforded to prune the trees, by which matured Peach-orchards may be benefited. It may be best done on what may be styled the "renewal system" of pruning. This means to remove the entire head of the tree.

It is the habit of this tree as it enlarges its growth to set the bulk of its fruit at the extremities of its branches, which are often broken by its weight. As Peach-orchards are usually managed, or mismanaged, a full peach crop generally causes the ruin of many of the trees. After a bountiful harvest a Peach-orchard sometimes looks as if a tornado had swept through it. We see naked stumps of Peach-trees from which all the limbs have been torn by the burden of an excessive crop of fruit. This may be Nature's system of pruning the Peach, but from observing it many years ago I learned to improve upon Nature by the practice of a more orderly style of pruning.

After the growth of the Peach-tree starts in April, and the leaf-buds have opened, saw off all of the limbs of the tree to within, say, two feet, or even less, of where these branch from the trunk. The tree will then form an entire new head, and in one season make a growth of six or eight feet of new wood which will set fruit-buds and may bear fruit the next year. I have thus renewed and re-renewed an orchard of twenty acres of Peach-trees, securing by this treatment finer fruit, which was more easily gathered, and securing the trees from damage by breakage of limbs from the load of a crop. After the trees have borne two or three crops, and their branches become elongated, pass through the orchard, shortening in the heads, as above described, of alternate trees in the rows. The next spring do the same to the trees left unpruned the year before. The orchard may then be allowed to grow as it pleases for some years, after which the tree-heads may be again shortened in alternately as before.

The Cherry and other stone fruits may be similarly treated, with advantage to the tree and great improvement of its product. This tree-pruning should be deferred until growth has fully started in spring—from April 20th to May 20th. If the tree be thus headed in during winter, or while its vitality is dormant, it may never awaken into life; but its branches may be all removed after vital action is begun without harm to the vigor of the tree. In fact, it is a good rule to practice all kinds of pruning when a new growth has begun to develop. Many horticulturists consider it imprudent to thus remove all of the limbs of a tree at one operation. They argue that it may give a shock to the tree's growth, from which it may not recover; therefore it is generally advised in top-grafting to remove a portion only of the branches at once, deferring removal of the rest until the next year. Such has not been my practice. In forming a new head to the tree by pruning or by grafting I have invariably made an entire decapitation at once, and during the past forty years I have found this practice always satisfactory.

Vineland, N. J.

Alexander W. Pearson.

Grapes for Everybody.

MR. WILLIAMS' list of Grapes is so good that I feel inclined to add some notes from another soil and climate. I should, for general planting, exclude Cottage entirely and Moore's Early almost wholly, and would moreover advise every one to plant Worden alone for a black grape. I see no reason for planting Concord any longer. Worden is equally hardy and prolific, and is of better quality. It is sweet as soon as colored and hangs well on the vine. It is a capital keeper, much better than Concord in this respect. It has the thin skin of the Concord class, but does not break so easily. A cross between Herbert and Worden would be nearly perfect. Why, then, shall we not adopt Worden as for the present our ideal black early Grape? For late black I would place Herbert ahead of Wilder and the rest. But if a really very early black Grape must be had, Moore's Early is so far our best with me.

For red grapes I agree in selecting Brighton if planted with other vines to supply pollen. But next to it I should name Gærtner, one of Rogers' hybrids not at first appreciated. Lindley is a fine Grape, about as good as Massasoit, which Mr. Williams does not mention, and not quite as early. I should make my list of reds Brighton, Gærtner, and Salem, I think.

For white grapes I do not hesitate to take Diamond for the head of the list. I think it is sufficiently tested and by the best judges in all parts of the Union. I have not seen one severe stricture on its quality, growth, habit or bearing qualities. Lady, at last, I am compelled to discard. It yields no crop to speak of. It is my ideal grape in quality, but it will not prove itself even a decent vineyard grape for cropping. Niagara I class with Diamond. But Hayes is very fine indeed and perhaps we shall learn to rank it first or second, for Niagara mil-dews very easily. Duchess I should not hesitate to include in the list, were it not tender. It must be covered; but in quality it is delicious. Pocklington is a grand grape when dead ripe, but it is too often sold and eaten when only half ripe. Empire State is nowhere near as good as it ought to be. Martha, if thinned sharply, is fine; otherwise, poor. I make my list of white grapes Diamond, Hayes, Niagara and Duchess.

Now for special purposes there is another list necessary. Iona is unequaled for a red grape if protected. Goethe, if well placed in a sunny spot, is also delicious—late and a grand keeper. Jefferson, if well ripened, is superb. For arbors, barns, etc., August Giant is a remarkably rampant grower, prolific and quite a good grape. Eldorado is a fine grape, unsuited for general planting, but a vine or two deserve a place. Mr. Campbell, of Delaware, Ohio, will offer us before long some new hybrids, some of which by his favor I am testing. I am inclined to think our progress in grape improvement is nowhere near its end. The points already achieved are size, prolific bearing and hardiness. We should work to eliminate seeds largely. Most of the Rogers' hybrids are very seedy; Jessica is little else. Diamond is a great improvement in this direction. Iona, with its small seeds, is nearly perfect in all points but in hardiness. Goethe is the nearest approach to the hot-house grape, but it is too late for the Northern States, except in very favored spots. Let me add that success with Grapes depends more than all else on a high, well drained soil.

Clinton, N. Y.

E. P. Powell.

The Babianas.

THE Babianas are a very pretty genus of bulbous plants, natives for the most part of the Cape of Good Hope; they all have long and narrow leaves, folded lengthwise like those of some Palms and covered with fine hairs, except the small species, *B. Socotrana*, whose leaves are smooth. They are of very easy cultivation, needing to be potted in September in a light soil and to have plenty of water, sunlight and air. The temperature of an ordinary greenhouse is sufficient for them. Thus treated they will be in flower in February, and being from their plaited leaves and the color of their blossoms unlike other Cape bulbs, they furnish an agreeable variety and never fail to attract attention.

Like most bulbs from the same country they are hardy enough to do well in a cold frame if there is not room for them in the greenhouse, and so treated they flower very finely, but at a time when Scillas, Narcissi and Muscaris are plentiful. I have a long row of them now (April 21st) about five inches high in a frame, which in about two weeks will be in blossom.

There are about twenty species known to science, some of which are not in cultivation and many of the others not to be had of ordinary dealers; for even the Dutch wholesale dealers and growers can supply only four or five species at the most, and those often incorrectly named; the remainder of the "fifteen most beautiful sorts" offered in their catalogues are

seminal varieties of *B. stricta*. The only way known to me of obtaining the greater part of the true species of this and other genera of Cape bulbs is to order them from the sales division of the Cape of Good Hope botanic garden, which by the niggardly policy of the government is compelled by this means to make up for a miserable half-appropriation.

B. sambucina is one of the best species, horticulturally speaking; its flowers are large and showy, purple with a dark line traversing each division of the flower. It is strongly perfumed with the fragrance of the Elder, and like many other species, produces auxiliary bulblets. *B. spathacea*, *B. tubata* and *B. tubiflora* are very curious and interesting when in flower, but the blossoms are inconspicuous and produced on very short stalks, so that the plants frequently bloom unobserved by those who pass them daily. The flowers of these three species have tubes four inches long and their colors are straw or cream or faint purple. *B. disticha* also has light colored flowers, produced on spikes six or eight inches long, and the plant is well worth growing. *B. plicata* with large purple and yellow flowers is one of the finest kinds.

Mr. Baker considers the plants known as *B. villosa*, *B. rubro-cyanea*, *B. obtusifolia*, *B. purpurea*, *B. sulphurea* and *B. plicata* mere varieties of *B. stricta*, and I know from experience that some of these may be raised from the seed of that species.

bell-glass, say, or in a propagating frame. Plants from seed require somewhat similar treatment, but need a little watching when quite small, because much moisture on the foliage causes them to damp off. *Bertolonia marmorata* is an old favorite, and, though not quite so showy as some of the more recent introductions, yet is well worthy of cultivation. It has ovate, slightly hairy leaves of a light green color, and variegated with irregular markings of white, the under side of the leaves being purplish. This plant has also been known as *Erianema marmorata*, and is a native of Brazil.

Bertolonia margaritacea is another excellent sort, and, though very pretty as an individual plant, is more effective when several are massed in a pan, which is decidedly the best way of growing for exhibition. *B. margaritacea* produces leaves from four to six inches in length, olive green in ground color and ornamented with lines of pure white spots.

B. superbissima, while resembling the last named in some particulars, is even more beautiful, the spots on the leaves being bright pink and the under surface being uniformly colored with a similar tint.

But the gem of the genus is a hybrid of garden origin, *B. Van Houtteana*, which has the largest foliage and the brightest variegation as well. This consists of streaks and dots of purplish pink or magenta, which contrasts effectively

Bridge at Topsfield, Massachusetts.—See page 211.

Some of these forms are very beautiful. *B. plicata* is white or nearly so; others have the divisions of the flower alternately white and purple or yellow and purple; another is very dark purple with black blotches. *B. rubro-cyanea* is a very striking flower whose colors are blue and crimson, much like those of *Geissorhiza Rochensis*. The genus is said to be named from the Dutch word for baboon, because the animal feeds upon the bulbs of these and other plants.

Canton, Mass.

W. E. Endicott.

Bertolonias.

THE Bertolonias form a group of beautiful small-growing stove-plants, their simple ovate or obovate leaves being remarkably attractive on account of varied colors and markings. The flowers are not of any special value, the chief beauty of the plant being found in its foliage, and unless seed is desired it is best to pinch out the flowers as they appear, as their perfection is usually attained at the expense of the foliage, which suffers both in size and vigor if the flowers are allowed to develop. The Bertolonias luxuriate in a warm, moist house and should be well shaded, as the foliage is too tender to endure full sunlight. They are readily propagated from seeds, or from cuttings, which root freely if placed in a good bottom heat and kept rather close for a time under a

with a ground color of olive, and forms a combination seldom equaled among variegated plants. These four varieties would make a good beginning for any one who wishes to try this class of plants, though several others may be added to the list if desired—for instance, *B. guttata*, *B. Mirandæi*, *B. Marchandii* and *B. vittata*, all of which are good.

Bertolonias prefer a light, open soil of equal portions of peat or leaf-mould and loam, with enough sharp sand to make the compost open and easily drained. The pots or pans should be well supplied with drainage material, and the plants liberally watered, though it is advisable to keep the water off the leaves as much as possible, and especially so during the winter.

W. H. Taplin.

Hardy Plants for Cut Flowers.—II.

A MOST useful spring-flowering plant is *Trillium grandiflorum*, the best of the genus, owing to the size of its flowers and their pure white color when first opened; this, however, turns to purple with age. *T. ovatum* and *T. stylosum* are both good, and also white. Trilliums usually appear to the best advantage when well established, and this is usually the second or third year after planting. They thrive best in a shady position, and a virtue may be made of necessity by

planting them under trees where other things would not succeed. For naturalizing in such places Trilliums are invaluable. If the growing of hardy plants under glass were advisable, Trilliums might be so treated and flowered a month earlier, as is often practiced in England. But, as a rule, plants that are thoroughly hardy are more enjoyable when flowering at their own sweet will than when forced into attenuated and premature bloom under glass.

Doronicums have lately come into favor for cut flowers, and justly so. They are not only well adapted to this purpose, but they rank among the choicest of early summer border-flowers. We have tried five species and varieties, all of which are perfectly hardy. *D. Caucasicum*, *D. plantagineum excelsum*, and, where it will thrive, *D. Clusii*, are three of the best sorts. Of the variety Harpur Crewe we have had no personal experience. Regarding the culture of Doronicums, one thing should be borne in mind—they do not like any soil other than that of a retentive nature, and this was noticeable even in a summer like the last.

With the first appearance in April of its elegantly cut foliage, *Dicentra eximia* commences to bear deep rose-colored, nodding flowers on stems a foot long, which may be gathered from April to the end of October. *D. eximia* is a native of the southern Alleghanies, but it is perfectly hardy, and without the disagreeable odor so noticeable in others of the genus. There are few other hardy plants that flower continuously six months of the year. *Helenium Hoopesii*, another native plant and a composite, is a showy and useful border-plant, not so well known as it should be. *H. Hoopesii* grows two feet high, and bears numerous bright orange, Daisy-like flowers in early summer; its culture is of the simplest; any ordinary border-soil will suit it. *Daphne Cneorum*, though not a herbaceous plant, is usually included among collections of such, and certain it is that there are few plants so worthy of being in every garden, both for the fragrance of its blossoms and the freedom with which they are produced nearly all summer. We have noticed, however, that this *Daphne* is a trifle more exacting than many other plants as to the soil it is to be grown in. We are told that it is indigenous to southern Europe among rocks, in gravelly soil with plenty of humus, and it will be found that if, when planting *Daphne Cneorum*, this is borne in mind, and anything approaching a heavy, wet soil avoided, the plants will grow rapidly with no further attention, and yield abundantly its delicate pink blossoms. The Trollius, or Globe-flowers, resemble gigantic Buttercups, and flower in the early days of summer. *T. laxus* is common in wet meadows in the Eastern States, and is well deserving of cultivation. The sepals of this and the next species are concave, forming a kind of globe, hence the common name. *T. Europæus* grows a little taller than the last, and is usually eighteen inches to two feet high, and has very large yellow flowers. *T. Japonicus* has bright orange colored flowers, and is a distinct species. The above three form a pretty group in a moist soil in the open border. We have found that Trollius-seed sown under glass, and carefully protected, does not germinate in two years. The next seed was sown when gathered, and was well frozen in a frame in winter, and it germinated promptly with the coming of warm spring weather. These remarks apply to many other seeds, such as those of *Anthericum Liliastrium*, *Gentiana acaulis*, *Gillenia stipulacea* and *Allium Karataviense*.

Passaic, N. J.

E. O. Orpet.

Notes on Wild Flowers.

Asarum Virginicum (Wild Ginger), which has been in flower for more than a week, is a valuable plant for a shady location. The flowers are not conspicuous or showy, but the foliage is very pretty, and it endures through the winter, appearing as fresh in early spring as at any season. The leaf, nearly round-heart-shaped, is shiny above, often mottled with white, and of a thick, leathery texture. The plant is hardy, easy of culture and conspicuous in early spring because of its fine foliage. It is a native of Virginia and other southern States around and among the mountains. *A. arifolium* is another species from the south with much the same kind of foliage, but not so thick as that of the former. The leaves are larger, halberd-heart-shaped, dark green, often blotched with white or lighter spots. They endure through the winter, as do those of *A. Virginicum*, and should be grown in the same location.

Few of our native plants reward the cultivator more bountifully than the Hepaticas (*Anemone Hepatica* and *A. acutiloba*). Both are hardy, are not difficult to grow, and give a profusion of flowers of various shades and colors in early spring when there are but few other plants in bloom. The foliage is also fine on strong, well established plants and endures through

the winter. Hepaticas can be grown in the shade where most plants would not thrive, or in a fine loamy soil they do well in full sun light.

The Pasque flower (*Anemone patens*, var. *Nuttalliana*), just flowering, is one of our finest native Anemones. It is a native of the western prairies, but thrives well in any moist, well drained soil in the sun. Its earliness makes it the more valuable. In strong, well established plants the flowers are three inches wide, light purple or almost white in color. They open in the warmest portion of the day and close at night, and endure for several days. They appear before the leaves, and a bed of these plants has a strange appearance when covered with large, erect flowers without foliage.

Southwick, Mass.

Orchid Notes.

MAXILLARIA LEPIDATA.—In a descriptive note on this Orchid (see page 127), Mr. M. Barker asks if the plant he describes is the same as what is grown at Kew under this name. His description might have been made from the Kew plant, except in regard to size, the latter being a large one, over a foot across; it flowers freely every year in March. Lindley's description, referred to by Mr. Barker, appears to have been made from imperfect material, but he used the word *acaulis* as indicating the section of the genus to which *M. lepidata* belonged—i. e., those species characterized by the pseudo-bulbs being clustered, and showing no distinct stem or rhizome. To this group belong all the best of the garden Maxillarias—namely, *M. luteo-alba*, *M. grandiflora*, *M. nigrescens*, *M. picta*, *M. venusta* and *M. Sanderiana*. All these have ovate pseudo-bulbs, large strap-shaped leaves and erect one-flowered racemes.

A second group has the flowers in short, compact racemes, and is represented by *M. hyacinthina*, *M. leontoglossa* and *M. elongata*. These have lately been removed from Maxillaria into a separate genus—namely, *Xylobium*. The third group includes all those with distinct rhizomatous stems, such as *M. variabilis* and *M. purpurata*. Altogether there are about 120 species of Maxillaria known, but only a few of them are of any value as garden plants.

ANGRÆCUM CITRATUM is one of the prettiest of small Orchids. It has short, tongue-like, bright green leaves resting on the soil, and, springing from their axils, the most elegant spray-like spikes of flowers, some spikes being a foot long. The flowers have long spurs and a flattened arrangement of the segments, which are nearly an inch across; their color is a pale cream, almost white, with a pale bluish shade on the labellum. They are arranged in two perfectly straight rows, one on each side of the spike, and they are so pure, so elegant, and, withal, so lasting in freshness, that we know of no plant, Orchid or other, with which to compare them. The species is a recent introduction from Madagascar.

Kew.

W. W.

HEUCHERA SANGUINEA.—Lovers of beautiful rock-plants will be pleased to learn through Mr. Orpet's note of the hardness of this plant. I have still further evidence of its hardness. Seedlings raised during 1887 withstood the winter of 1887-'88, which will be remembered as a severe one. Considering the ease with which this plant may be propagated, it should become common, and be sold cheaply for forcing, for which it is as well adapted as the common *Astilbe Japonica*. Seeds sown as soon as ripe and wintered in boxes in a cold frame come up early the following spring. I have adopted this plan of sowing seeds over winter with much success, especially with slowly germinating species of Columbines. *A. glandulosa*, if sown in this way, germinates freely and is just as easy to manage as any of the common kinds, while if sown in spring sometimes three-fourths of the seed will lie over, or come up straggling all summer.

GROWELL.—I am also pleased to be able to record the hardness of the Growell, *Lithospermum prostratum*, a trailing, semi-shrubby Boraginaceous plant, with pretty blue flowers, exceeding in intensity of color the Forget-me-not, and rivaling the Virginian Cowslip, *Mertensia Virginica*. This plant is easily propagated by soft-wood cuttings. It will not thrive in a wet place.

LENTEN ROSES.—We set out a number of these plants in grass under a spreading Hickory last summer after being forced, and were delighted to find all in bloom on April 3d. A splendid effect could be produced by planting in this way some of the fine hybrids like Willy Schmidt, Hofgarten, Inspector Hartweg, Commissioner Benary, Frau Irene Heinemann, *Helleborus colchicus*, *H. purpurascens* and others. I should not care to risk *H. niger*.

Hydrangeas.—It is common to see large specimen plants of *H. hortensis*, but small ones are rare. Few greenhouse plants are so easy to grow and so useful in a small state. Cuttings taken in spring from half matured shoots root readily almost anywhere. Superfluous shoots broken off will sometimes take root on the benches. When rooted they can be planted out-of-doors, where, with abundance of water and sometimes a little liquid manure, they will make nice plants by the fall. They may be taken up and potted into six-inch pots, and if kept cool and moderately dry they will ripen their wood, in which state they may be kept until wanted, say in February, for forcing. A night temperature of fifty-five degrees is sufficient, with abundance of water and a light position.

Wellesley, Mass.

H.

Seasonable Hints.—Most forehanded gardeners in this latitude are well along with their early spring work and yet those who have been delayed by unfavorable circumstances can still begin with every assurance of good returns for their labor. Where early vegetables are appearing the crops should be thinned out as soon as the plants are large enough. Novices too often forget that each plant requires room for development, and that a square foot of soil will support only a certain amount of vegetable life. Radishes should be thinned until they stand two inches from centre to centre. Beets should stand four to six inches apart; Onions three inches; Lettuce from six to ten inches, according to the size of the variety; Carrots from three to four; Spinach, for the spring crop, three to four inches; Turnips four to six inches. Of course Peas and Beans do not require thinning, while Cabbage, Cauliflower and Celery are to be transplanted, and the first two should stand in rows three feet apart and eighteen inches apart in the row. Stirring the soil should begin as soon as the plants make their appearance. This is not only to pulverize the clods and make all the plant food available to the young roots, to admit air into the soil and to open it so that it will drink in the rain, but it is the only time when the weeds can be successfully subdued. When the weed-seeds have just germinated a little disturbance and exposure will destroy them and make after-cultivation much more easy. Successional crops of Peas, Beans, Lettuce and other vegetables sown earlier should be put in, but it is yet too early to plant Corn, Lima Beans, Melons or any other tender vegetables in the open ground. The conditions of early spring have lingered so long that small fruits may yet be planted. They should be severely pruned, because the rapidly increasing temperature will hurry forward the leaves before the roots are prepared to supply them with adequate moisture. Tobacco dust mixed with half its bulk of insect powder and sifted on Grapes, Currants, Raspberries, and in fact on all the shrubs of the garden which are developing foliage, will help to keep away numerous insect pests. The dusting should be done while the dew is on the leaves.

The Flower Garden.—The season is still young enough for planting hardy shrubs and herbaceous plants, if the precaution is observed to head in shrubs more severely than is necessary earlier in the year. Be in no haste to set out tender plants. Those which are purchased are generally taken from under glass, where they have not been hardened off, and a raw wind or a chilly night will give them a shock from which they will not recover all the season. In selecting varieties, novices should confine themselves to old and well-tested kinds. So called "common" flowers and shrubs have become well known because their merits have been established after years of trial and selection. They are invariably good and effective, and they are usually better than more recent introductions. The testing of novelties is one of the pleasures of gardening, but the experimenter will be disappointed if he hopes that many of these new acquaintances will be as worthy of care as the old and standard occupants of the garden.

Correspondence.

The Noxious Primrose.

To the Editor of GARDEN AND FOREST:

Sir.—Perhaps a few notes on the irritation of the skin by *Primula obconica* may still be in order. The plants on which my observations were made were fully developed specimens, and had been propagated by division of last year's plants—not raised by sowing seeds after the more natural method. About five hours after the work of picking dead leaves and flowers from about a hundred of them, the backs of the hands and portions of the arms began to itch, and a slight swelling of the parts affected was noticeable some five hours later.

The swelling disappeared in twenty-four hours, but the irritation was not wholly gone until the seventh day. It was very slight at its most acute stage, while the swelling caused no inconvenience whatever. The application of soap and water to the affected parts hastens and increases the irritation. Moisture appears to aid the injurious propensities of the plant, for it is noticeable that the irritation and swelling are more severe when either the skin or the plant is wet.

A good botanical dissecting microscope fails to reveal any trace of vegetable hairs in the skin after contact with the plants; and this fact suggests the belief that the plant secretes a poisonous fluid. The irritation differs from that caused by minute spines entering the flesh. In the latter case a sharp sense of pain is experienced, and, guided by it, each individual spine may be located; but in the former, larger surfaces appear to be affected. I have consulted with several persons who have grown the plant in quantity, and a few others have experimented at my request, so that I have information concerning its effect on thirty-nine persons. From the facts, I have calculated that about fifty per cent. of those who work among the plants are subject to their peculiar effects. Temperament and complexion appear to be unimportant factors in the matter; but two colored men whom I persuaded to test the plants remained wholly uninjured after prolonged contact with them. The experiences of some white gardeners and florists are similar to those of these two colored men, no amount of contact with the plants affecting them in the slightest degree. The irritation varies in intensity, and in some cases it is extremely slight. It is generally confined to the arms and backs of the hands, but there are important exceptions to this rule. Mr. K. Finlayson, a gardener at Brookline, Massachusetts, had his eyelids affected, though no part of his face had come in direct contact with the plants. He had been cleaning a number of plants, and his hands, he says, which were also affected afterward, may have been brought in contact with the face while that operation was proceeding. Mrs. M. H. Hutchins, a florist of North Cambridge, Massachusetts, had a similar experience. Mr. Finlayson believes that the hairs which clothe the flower-stalks are in some way the cause of the injury, and says: "My belief in this is strengthened when I remember that I can handle all other parts of the plant with impunity." Plants raised from seed appear to be less injurious than those propagated by division of the old plants; indeed, I have yet to find a case in which the irritation can be traced to one-year-old seedlings. Perhaps the hairs grow harder and sharper, or more virulent, as the plants grow older? It is somewhat difficult to get reliable information on this point, as the plants are propagated by both methods and mixed in most establishments. Seedlings do not injure Mr. Finlayson, though he is particularly liable to be affected by the older plants. Some further information on this phase of the question would be very desirable.

Botanic Garden, Cambridge, Mass.

M. Barker.

Nepenthes and a Gardeners' Problem.

To the Editor of GARDEN AND FOREST:

Sir.—Mr. Burbidge's interesting note on the exact climatic conditions in which he found *N. Rajah* and *N. villosa* serves a double purpose. First it proves that I was in error when I stated that *N. villosa* was in cultivation, the plant grown in gardens under this name being, as he points out, *N. Vietchii*.

In the second place, the particulars given by Mr. Burbidge in regard to *N. Rajah* form, when placed by the side of what was stated recently in GARDEN AND FOREST (see p. 108) and what I have since learned in England in relation to the cultivation of this Nepenthes, the strongest possible testimony to the truth of the statement that botanical science (including, of course, geographical botany) affords little information as to the best methods of cultivation for many plants. It is clear from what Mr. Burbidge says that in a state of nature *N. Rajah* grows only at high elevations and in conditions such as he says clearly indicate that under cultivation a lower temperature is necessary for this species than for the others. Mr. Moore's own story of his success with this plant, as quoted by Mr. Barker in GARDEN AND FOREST (see p. 146), proves that cool treatment is not disagreeable to it. But it appears now that while we here have been struggling to overcome the difficulties at first attendant on the cultivation of *N. Rajah* (it is just possible that some knowledge of the natural conditions put most people here on the wrong tack!) you in America have had it "flourishing for several years in stove-houses along with other Nepenthes, forming pitchers freely and flowering, no trouble having ever been found in its management."

Truly there is a great deal more to be got out of this question of cultivation versus nature than we have seen yet. I learn from Messrs. Vietch that although they could not manage *Nepenthes Rajah* anyhow when they first received it, yet now they find no difficulty in making it grow and pitcher freely in the same house which contains the general collection of *Nepenthes*, and where when tried a few years ago it obstinately refused to grow! This behavior is not an uncommon occurrence with new introductions. Of course we must believe that some essential condition had been absent when failure was the result, and had been included by accident when success was attained.

A comparison of the plants grown by a market-grower in his "rough and ready way" with those of the same kind produced in well equipped gardens generally places the former a long way first. The market gardener has hit upon the conditions essential to the healthy growth of his plants, hit upon them by experiment most likely, whilst probably the "scientific" cultivator has taken a lot of pains to afford the conditions about which the plants are probably indifferent and omitted those upon which everything depends.

Kew.

W. Watson.

The Study of Botany.

To the Editor of GARDEN AND FOREST:

Sir.—I have been much interested in your various articles advocating the study of botany by young people, and think you may care to print the following sentences as an indication that those who are best qualified to speak on the subject of education are in agreement with your views. I quote from an article called "Education in Boyhood" by President Timothy Dwight, published in the April number of the *Forum*:

"I would most heartily respond also to the words of the gentlemen of the Society of Naturalists who have addressed a paper to the teachers of schools and colleges in which they commend with special emphasis the study of botany and physical geography for the years of school life. The knowledge of botany gives a joy which should be in the possession of every educated man, and should be gained, as it easily can be, in the early youthful season. Science everywhere brings us into a close relation with nature. The boy in his first days of growing boyhood is open to all the sympathies which this relation bears with itself. Let him by all means have the sympathies awakened. He may not indeed be able to penetrate very deeply into what nature has to reveal to him, but he may see with delight all that he can as yet understand. . . . The beginning is never to be lightly thought of, because it has not the fullness of the end. . . . There is cheerful hope for the youth whose mind and heart are stirred with love for all the truth and beauty hidden in the natural world."

Pittsburg, Penn.

W. G. R.

Hardy Plants at Passaic, New Jersey.

To the Editor of GARDEN AND FOREST:

Sir.—Hardy plants are such general favorites that a few notes of a hurried visit to the nursery of Mr. Henry Meyer (successor to Woolson & Co.), at Passaic, New Jersey, may be of interest. Mr. Meyer has lately removed to a property several hundred feet north of his former grounds and now has ample room to develop his growing business. The nursery fronting on the Passaic River and extending back with several acres of plateau, embraces also a wood-covered slope which is being utilized for the naturalization of suitable plants. The houses are long, low, ten-foot spans, especially built for the propagation and protection of hardy and half hardy stock, no tender plants being grown. Though great spaces have been made in the benches by early shipments of plants, all the old favorites and many new ones were to be seen by scores and hundreds. Mr. Orpet, the skillful propagator of the establishment, is an enthusiast in hardy-plant culture, and here may be seen seedlings of many plants under trial that their merits may be tested before they are sold. Of course in a nursery of this kind little effort is made to grow flowers, but many interesting ones could be seen. *Primula verticillata* is a gem—a strong growing species from Abyssinia with fragrant yellow flowers. The leaves are large, four to five inches long and covered profusely with "meal"; altogether a charming variety, although of course requiring the protection of glass and attention in the way of careful watering. *P. cortusoides* is also a very satisfactory species just coming into bloom. This also seems happier in a house or frame. *Dianthus latifolius* was a mass of rich, large, crimson blooms. If this variety proves as continuous a bloomer as it now promises to be it will be a first rate garden plant. Pinks usually have

much too short a blooming season. The Clove Pinks were here in great variety, but "Paul Engelheart" with its great crimson flowers on rigid stems was the only one in bloom. The Drabas are neat little alpine plants. Two good ones are *D. bruniifolia* (Caucasian), which was showing its yellow flowers above dense mats of light yellow foliage, and *D. cuspidata*, with its attractive bronzy rosettes. A new alpine is the double-flowered *Alsine verna*, which forms carpets of very fine dark green foliage, studded with pure white small double flowers. It is a gem for the rockery.

In the frames were blooming *Isohyrum biternatum*, a charming native plant with the aspect of the little wood Anemone. *Anemone Apennina*, with its beautiful blue flowers, was in full bloom, following closely *A. blanda*, whose season has ended. Shortia established in pots showed its lovely white flowers. White Violets and *Phlox subulata* made charming bits of color. In the fields the hybrid Hellebores were still in bloom, quite uninjured by any weather changes. Polyanthus and Auriculas were of course in force. Unless for trade purposes it seems a mistake to grow the former of these in frames, as on a well drained border they are perfectly hardy and much more floriferous than the plants protected by frames, where their energies seem to tend more to the production of leaves. Alstroemerias are favorite plants here, *A. aurantiaca* and *A. Peruviana* being established in warm quarters, while the somewhat rare *A. peregrina alba* was opening its pure white blooms in one of the houses. A large breadth of *Chionodoxa Lucilia* was a brilliant picture in blue, rivaled by the light blue flowers of *Scilla puschkiniioides*, one of the best of the early Squills. Narcissi are grown in great abundance, Mr. Woolson in former years having had a very large collection which he was wont to exhibit at the shows of the New York Horticultural Society. The collection is somewhat reduced now and comprises principally the bold growing kinds of the most esteemed varieties. Henry Irving and Sir Watkin had passed out of bloom, but beside a grand lot of Horsfield's variety in its prime, the numerous other kinds seemed only fair, though favored with all the fashionable names.

Time was too limited to investigate the treasures of the hill-side, where it would seem that many shade-loving plants could be grown very successfully; but it was pleasing to see testimony of the growing demand for well known plants in the great stock of Aquilegias, Artemisias, Phloxes, Irises of all kinds, *Corceopsis lanceolata*, *Erica carnea*, *Daphne Cneorum*, *Anemone Japonica* and scores of other sterling old-fashioned kinds among the novelties of promise.

G.

Recent Publications.

The Garden, as Considered in Polite Literature; with a Critical Essay by Walter Howe. New York: G. P. Putnam's Sons.

Inside and out this is one of the most charming little books ever presented to lovers of gardens. As it forms the twenty-seventh volume of the Messrs. Putnam's well known "Knickerbocker Nugget Series," the character of its pretty binding and delicate typography do not need particularly explanation. The essays it contains begin with Pliny the Elder's "Pleasures of the Garden," which is followed by his nephew's famous descriptions of his two country-seats, types of the more modest and the most sumptuous kinds of Roman villas. Bacon is the next author quoted, with his delightful little paper "On Gardens," and Sir William Temple follows. Then come three essays from the *Spectator*, two by Addison, and one which has been variously attributed to Pope and to Dr. Parnell. A chapter of Pope's from the *Guardian* and Lady Mary Wortley Montague's "Letters to the Countess of Bute" succeed; and then we have extracts from Whateley's "Observations of Modern Gardening," from which is usually dated the rise of our literature dealing systematically with gardens of the modern, natural, landscape sort. Oliver Goldsmith's "Description of a Chinese Garden" and "History of a Poet's Garden," and Horace Walpole's little biography of Kent and "History of the Modern Taste in Gardening" are then given, and the book concludes with John Evelyn's "Of Fences and Quickset Hedges," which is placed out of its chronological position, yet wisely, as it differs from the other essays in being of a less general character.

All these essays are of course familiar to students of literature and of the history of gardening. But even to readers of this kind their association in a single volume will give them a fresh charm, and they will undoubtedly be new to many whose interest in gardens has been of a practical rather than a literary sort. But their value to either class of readers would have been far smaller without the delightful and in-

structive essay with which Mr. Howe has prefaced the book. Modestly called an "introduction" it is in fact a masterly little sketch of the history of gardening in which many authors are quoted who have no place in the body of the book, while the historical significance of those who have such a place is made clear. Especially interesting are the passages which explain that different styles of gardening have developed since the seventeenth century although we are accustomed to mass them together under the general name of the "naturalistic" style; and also those which lay stress upon the progress of the art in recent days and the greater difficulty of the tasks laid upon the modern designer as compared with those of his predecessors. "The ends of the earth," says Mr. Howe, "now contribute a wealth of plant life adapted to useful and ornamental tree and shrub-culture and to decorative horticulture. Their habits and relative value in a landscape effect, or in a garden, must be familiarly known and felt by an artist who may be called upon to make studies for a lodge in Scotland, a villa at Cannes, or a park in Australia; who may be required to bring back the primitive verdure to the banks of Niagara, to preserve the natural beauties of the Rockies, or to plant the plains with the forests they can and should be made to support. The rich flora of China and Japan have now been acclimated in Europe—and even more successfully in America—and the enormous number and variety of trees, shrubs, herbaceous and other plants now added to the resources of gardening call for correspondingly greater learning and training than has ever before been given to the subject, so that the accomplished landscape artist of to-day is as far beyond the Kents and Le Nôtres of the seventeenth and eighteenth centuries as they were beyond the topiarius who tortured the trees and shrubs of Pliny and the Cæsars."

Nothing could be more judicious than the following remarks with which our brief notice of this delightful little book must close: "Two qualities which usually distinguish professional from amateur productions in art—namely, simplicity and breadth of treatment—are especially important when applied to the face of Nature itself. True, Nature will, in course of time, protect herself from the misguided assaults of well-meaning amateurs by covering up or wholly destroying their abortive exertions. A trained artist, on the other hand, knows how to assist Nature without resorting too bluntly to the easy device of servile imitation. In such work, particularly as now taught and practiced, there is produced an impression of repose and well-balanced composition that is suggestive of natural effect and yet satisfactory as a work of art." How true this is, yet how constantly does the public admire a beautiful park for its "natural" charm, forgetting the fact that there is nothing like a park in Nature, and that it requires the very highest artistic skill to produce one which shall look as though Nature might have formed it.

Periodical Literature.

The most attractive articles in recent numbers of the *Century Magazine* have been three, written and illustrated by Mr. John La Farge, called "An Artist's Letters from Japan." The series will be continued, and promises to give the untraveled reader a more vivid and fresh idea of the land of Chrysanthemums than has hitherto been given in our language. The most interesting chapter thus far published appeared in March. Text and pictures are equally delightful, and together they emphasize various points with regard to the Japanese treatment of landscape and plants which, in a bolder fashion, have already been suggested to our readers. For example, the benefit that a beautiful view derives from some sort of foreground framing is admirably shown in one of the pictures where tall trees on steep banks draw close to the road, and it is spanned by a torii, through which the approaching eye perceives a wide plain, and as the centre of the picture a group of low buildings and trees. A torii, it should perhaps be explained, is composed of four bars, two set upright and two running across near together at the top, the upper one being curved with the concave side up. "This assemblage of four lines of stone or wood or bronze," writes Mr. La Farge, "is to me one of the creations of art like the obelisk or the pyramid. Most impressive, most original of symbolic entrances, whether derived from sacred India or from the ancestral ignorance of Polynesia, there is something of the beginning of man, something invented while he lived with the birds in this elementary porch, whose upper line, repeating the slope of hill and wave, first embodied the curve that curls all upper edges in the buildings of the farther East. . . . Looking through a torii one is sure to be in the direction of something sacred, whether it be temple or shrine or holy mountain.

Neither closeness nor distance interferes with this ideal intention, and the sacred Fusi-yama is often seen a hundred miles away in the sky, framed by these lines, built for the purpose." Well may the writer say that "the Japanese sensitiveness to the beauties of the outer world is something much more delicate and complex and contemplative, and, at the same time, more natural, than ours. Outside of Arcadia I know of no other land whose people hang verses on the trees in honor of their beauty, where families travel far before the dawn to see the first light touch of the new buds." Of the forests along the traveler's way, he says: "Sometimes there were traces of enclosure about these woods; sometimes they had no edgings but their own beautifully modeled contours. Long ages, respectful care, sometimes fortunate neglect, have made of these reserved spaces types of an ideal wildness, for these are sacred groves, and they are protected by the divine contained within them. This preservation of a recall of primeval nature, this exemption of the soil from labor, within anxious and careful tillage, is a note of Japan constantly recurring and a source of perpetual charm. . . . As the evening came on we crossed a large river and looked down from the height of the new bridges upon the discarded ferry-boats, and upon the shape of a more fantastic one that was never meant to sail—a Pine-tree, shaped and trimmed, spread its green mast and sails in a garden by the water." The famous avenue of giant *Cryptomeria*, twenty miles in length, that leads to the shrines of Nikko has often been described before, but these touches of detail show a true artist's eye: "Where an occasional habitation or two or three are niched in some opening, the tall columns of the great trees are interrupted by spaces filled with crossed branches of the wilder Pine, and behind these, outside, sometimes the light green, feathery mass of a Bamboo grove. Against the bank stood low thatched buildings; near them the great trees were often down, or sometimes dying; an occasional haystack, sliced off below by use, was fastened in thick projection around some smaller tree. Once, at a turn of the road near a building with a wide roof pushed against the corner-bank, out of a basin fringed with Iris sprung in the air a little jet of water. Near by a solitary ditcher had placed in a Bamboo fence some bright red blossom, with its stem and leaves, apparently to cheer him at his work." The picture called "The Waterfall in our Garden" is most interesting as showing how keen is the Japanese sense of fitness and harmony in gardening design. How often do we see Weeping Willows where they look badly themselves and hurt everything about them! So often that we have been tempted to feel that there can be no way of placing them well. But look at this picture and we see that in the lands whence they originally came they are charmingly employed. Here a narrow and very drooping one stands on a bank just beside the top stones of a little cascade. The falling water and the falling branches repeat one another's lines, and each feature gains by the presence of its neighbor, while behind the Willow lower trees of more normal shapes do not stand inharmoniously erect, but bend to form a sort of little arch above the waterfall.

A few weeks ago we noted some words of Mr. Charles Dudley Warner's, comparing the Rose and the sentiment it breathes with the Chrysanthemum, which, to his eyes, seems a mere showy, heartless and unpoetic plant. It is amusing to learn from Mr. La Farge that a Japanese might very well speak in just the opposite way of these two flowers. When he "smelled for the first time the fragrance of wild Roses, looking like ours but a little paler," he says: "This was the first thing which reminded me of home—the Roses that the Japanese do not seem to care for, do not seem to understand. With them the Rose has no records, no associations, as with us, for once on this side of the garden of Iran, the Peony and the Chrysanthemum, the Lotus and the Iris, the Peach, the Cherry and the Plum make up the flower poetry of the extreme east."

Recent Plant Portraits.

PHAJUS COOKSONI, *Gardeners' Chronicle*, March 29th; a handsome new hybrid, with nankeen-colored flowers, flushed with pink, raised from *Phajus Wallachii* and *P. tuberosus*, the former being the seed parent.

CITRUS JAPONICA, *Gardeners' Chronicle*, March 29th.

BEGONIA ADONIS, *Revue Horticole*, April 1st; a new winter-blooming hybrid of French origin.

Botanical Magazine, April:

PRESTOEIA CARDERI, t. 7108.

SICANA SPHERICA, t. 7109.

PELIOSANTHES ALBIDA, t. 7110.

IRIS ORCHIOIDES, *t.* 7111; a native of central Asia, and nearly allied to *Iris Caucasicus*, which differs from it in its dwarfer habit, by its thickened leaf margins and paler yellow flowers.

VANDA KIMBALLIANA, *t.* 7112; a beautiful and now popular Orchid, the secret of whose native country has been carefully preserved by the introducers, Messrs. Hugh Low & Co. Its nearest ally, *Vanda Amesiana*, is said to be a native of India.

Notes.

Over 200,000 acres of Florida land are said to contain deposits of phosphate. Much of the richest rock can be mined for twenty-five cents a ton.

The annual banquet given by the Trustees of the Missouri Botanic Garden in honor of Henry Shaw, the founder of that establishment, will take place in the Southern Hotel, in St. Louis, on the evening of Monday, May 26th.

It is encouraging to learn that at a recent meeting of the Colorado State Horticultural and Forestry Association two of the subjects which were most earnestly discussed were "The Ornamentation of School Grounds" and "Horticulture and Entomology in the Schools."

Two of the English horticultural papers just received speak with enthusiasm of hanging baskets filled with *Lachenalia pendula* now in bloom. The drooping habit of this plant both in foliage and flower, and its simple requirements (see vol. ii., pp. 28 and 30), fit it admirably for this use.

Mr. E. Tidmarsh, Curator of the Botanic Gardens at Grahamstown, Cape of Good Hope, writes that the cottony cushion scale, so destructive to Orange-groves in Australia and California, is probably a native of Madagascar. Missionaries report that it has preyed upon Lemon-trees there from time immemorial.

Mr. A. H. Curtiss, in the Jacksonville *Times-Union*, advocates the planting of the Camphor-tree in Florida in view of the increased demand for camphor as a necessary ingredient in the smokeless gunpowder which is likely soon to come into general use for purposes of war. The recent increase in the price of the gum suggests the idea.

This has been a successful season for nurserymen in California. Orange-growers have been forced for several years to depend largely on Florida stock, but the frosts this spring killed the young trees in Florida. The large acreage of Orange-groves planted last fall consumed all the local trees, and now there is a call for 120,000 Orange-trees that cannot be filled.

Monsieur Froebel, the well known nurseryman of Zurich, calls attention, in the *Bulletin De la Société d'Horticulture d'Genève* of Rose-growers, to the value of *Rosa laxa* as stock in the place of the Dog Rose, *Rosa canina*. Monsieur Froebel finds that *Rosa laxa* does not send up suckers, that its branches are very vigorous, almost destitute of spines and lateral branchlets, that the wood is hard with very little pith, and that the plants are exceedingly hardy.

Monsieur André, speaking in a recent issue of the *Revue Horticole* of the new seedling varieties of Clivia, which are just now attracting much attention in Europe, declares that none of the recent seedlings surpass or equal, perhaps, these four old varieties, Madame Van Houtte, Marie Van Houtte, Lindeni and Van Houttei. It is hard to believe, however, that they can equal some of the varieties which have lately found their way into commerce through the English nurserymen, notably Grandiflora and Veitchii, which are both certainly exceedingly fine in foliage and in the size and color of the flowers.

According to *L'Horticulteur*, there are one hundred and five gardens or squares in the city of Paris. About a million plants are used every year in their decoration, including 300,000 Geraniums, 60,000 Begonias, 33,000 Forget-me-nots, 33,000 Ageratums, 26,000 Azaleas, 7,000 Hyacinths, etc. These gardens are under the direction of Monsieur Laforcarde, the head-gardener of the city, who employs four hundred workmen in keeping them in order; the annual expenditure being only about 800,000 francs, which seems a very small sum in comparison with the amount spent in the care and decoration of the public gardens in this country, notably in Boston.

A bulletin issued by the United States Department of Agriculture contains a list of the horticulturists employed at the various stations, with notes regarding the work they have undertaken. Forty-two stations are named, but with regard to twelve no information is given. At seventeen stations, it is announced, special attention will be given to questions of synonymy; at two seed-testing will be systematically pursued,

and in several the improvement of native wild fruits will be one of the chief aims. Plant diseases will be generally studied, and new varieties of fruits and vegetables tested. Cultivators are asked to send in such varieties in order that their value may be ascertained.

A public meeting for the purpose of increasing the interest in Arbor Day and in forestry generally was held on Saturday, in the large hall of the Museum of Natural History, under the auspices of the New York State Forestry Association. General Viele presided, and B. E. Fernow, Chief of the Forestry Division of the Department of Agriculture, made the principal address, which was an admirable statement of the reasons for restoring and preserving the forests of the country. Other addresses were made by Col. Balch, Professor B. G. Northrup, Professor D. S. Martin, Chancellor McCracken, Doctor Stephen Smith and William Potts. The attendance was by no means as large as it should have been.

A Paris correspondent writes that the Perpetual Carnation Marguerite is being much talked of in the horticultural world. It appeared in France last year and a bed of it could be seen in the Trocadéro gardens during the exhibition. It belongs to a race of Carnations which, it is said, originated in Italy. Its principal merit is that it flowers the first year from seed. Seed sown under glass at the end of February give plants which, after having been pricked out, commence to bloom at the end of June and continue to give flowers throughout the summer and autumn. Indeed, it is said that the flowering season can be prolonged into the winter if the plants are taken to a cool greenhouse or placed in a frame. The Marguerite Carnation forms dwarf tufts about fifteen inches in height; its stalks are rigid, and their excellent habit recalls that of the so-called "Tige de Fer" Carnations. The flowers are large, well-formed and agreeable in odor; the petals are fringed, and, as regards color, show all the tones between pure white and brilliant red. Different varieties exist as self-colored, blotched and striped.

The *Gardeners' Chronicle* recently published a picture of a curious Chrysanthemum sport which appeared on a plant of the Source d'Or variety grown by Mr. Maries, of Lytham. One half of the flower-head consisted of "yellow, flat strap-shaped florets; the other of dark golden bronze florets, revolute at the edges. Such cases are always interesting and are susceptible of various interpretations. That which seems most plausible in this case is, that the appearance is due to the unmixing or separation of previously blended components. In the case of the Chrysanthemum, which has been crossed and recrossed and crossed again, for an untold number of years, it is evident that the breed must be very mixed indeed, and there can be little wonder if a 'return to first principles' occasionally occurs." This theory, added the *Chronicle*, is not susceptible of actual proof in the case of the Chrysanthemum. But it can be proved with regard to a sport of Veitch's Calanthe, of which an illustration was likewise given. This plant is known to be a hybrid between *C. rosea* and *C. vestita*. The diverse features of the parents are, as a rule, thoroughly blended in the hybrid, but in the single blossom in question certain features of each parent were combined in scarcely altered shapes.

The tariff discussion has brought out some interesting facts with regard to Flax production in the United States. More than a million acres in our northwestern states are annually planted with the Flax plant, but very little linen cloth, and that of the coarsest quality, is made here. A few mills are engaged in the manufacture of twine and thread from the fibre, but the Flax is chiefly grown for the seed, of which some thirteen million bushels are produced each year. The crop is raised on new ground, the seed being thinly sown, and, without cultivation, bearing a heavy yield of seed. When this is ripe the plants are cut by horse-reapers, the seed threshed out by a machine, and the straw burned on the ground. The fact that Flax is not grown here for its fibre is laid by some to the account of our climate as being too dry and hot for its best development, but by others to the great cost of cultivating the plant with such an end in view. In Europe each farmer devotes but a small plot to Flax, prepares the soil as carefully as for a garden-bed, sows the seed very thickly, and keeps the crop nicely weeded. The plants, coming up closely, grow tall and branchless, developing the fibre at the expense of the seed, and they are pulled up by the roots before the seed ripens. After this the fibre must be extracted on the farm by laborious hand processes, as it costs too much to send the Flax in bulk to the market. It will be easily seen that, even were our climate propitious, American farmers would be slow to engage in such a time and labor absorbing industry.

GARDEN AND FOREST.

PUBLISHED WEEKLY BY

THE GARDEN AND FOREST PUBLISHING CO.

OFFICE: TRIBUNE BUILDING, NEW YORK.

Conducted by Professor C. S. SARGENT.

ENTERED AS SECOND-CLASS MATTER AT THE POST OFFICE AT NEW YORK, N. Y.

NEW YORK, WEDNESDAY, MAY 7, 1890.

The Spring Garden.

IN these early May days the spring garden at the north, if it has been skillfully planned, is unfolding its choicest treasures, and is yielding a pleasure more intense than any which the wealth of flowers, the luxuriance of foliage or the fragrance and beauty of ripened fruits will bring as the season grows older. No later flowers cause such genuine delight as that with which we welcome the harbingers of spring. This is not altogether on account of their intrinsic beauty, although many of them are strangely fair; nor is it yet because they have so few rivals and occupy the field comparatively alone. Perhaps a stronger reason for the appeal they make to the imagination is the promise which they bring of a revival of life at hand—a promise especially cheering after our long and dreary northern winters. Besides this, there is a singular delicacy and fragility about those which first venture out into the wild weather, and this takes hold upon our sympathies. But whatever may be the causes of this universal manifestation, the fact remains that every one who has any admiration for flowers, or appreciation of them, is especially attracted by those which bloom out-of-doors in this early season. Many of these, like the Snowdrops and Winter Aconite, appeared before the grass began to show its first tender green, and now, when the branches of many of the trees are still bare, the spring garden is filled with flowers of the most delicate texture and richest color. Mere lists of plants are usually tedious, but a simple catalogue of even the commoner ones that have already flowered has a certain attractiveness. There is something akin to music in the very names of Anemone, and Scilla, and Primula, and Trillium, and Triteleia, and Uvularia, and Viola; and so there is in the common names like Snowflake, Wake-Robin, Grape Hyacinth, Fritillary, Wind-flower, Twin-leaf, Mitrewort and Violet. The variety of these flowers is almost endless. Collectors have ransacked all the temperate regions and high mountain ranges of the globe for

hardy, early-blooming plants, so that there is no place so pretentious that the spring garden cannot be made sufficiently elaborate and expensive to correspond with its other features, and there is no garden so modest that a corner of it cannot, with trifling labor and expense, be becomingly brightened with early flowers as beautiful as those borne by the most expensive rarities.

Now there are many persons who feel with each returning spring the charm which invests the flowering shrubs and herbs of the season, but the time for arranging the spring garden has then already passed, and later in the year when the bulbs should be planted, the beauty of the early flowers has faded from the memory and the matter is postponed until another year is lost. Of course, the proper time to begin garden work is now, in every instance. Plans cannot be laid too early. If a rock-garden is to be made—and many alpine plants will thrive better when their slender roots can find coolness and moisture in the deep pockets of well constructed rock-work than anywhere else—it is none too early to begin. Such a place can only be successful when the rocks are carefully placed, so as to check the flow of surface-water and allow it to percolate slowly into the soil between them. This soil must have time to settle and become compact, for any air-spaces mean dryness and death to root and plant. Another effective arrangement for a spring garden is where a southward sloping space of open greensward or a small lawn containing a few specimen-trees is surrounded by a shrub-border, and this border may again be surrounded by trees. These shrubs should be, as a rule, early flowering, with taller ones like certain of the Thorns, the Dwarf Apples and Lilacs on the outside, with Exochordas, Spiræas and Bush Honeysuckles and others of this size in front of them, and an irregular belt along the inner margin containing scattered groups of Azaleas, Daphnes, Andromedas, hardy Heaths and other low-growing shrubs. Between these shrub-groups may be set hardy bulbous plants and other perennials which bloom at the season. Such a garden can be made singularly effective when the curves which unite the turf with the border are gracefully laid, and when this margin is broken occasionally by some shrub like Van Houtte's Spiræa, set close to the turf, to relieve all appearance of formality by throwing its arched branches out upon the grass. A garden of this kind has already been described with some detail in this journal (see vol. ii., p. 277).

But no one need be deterred from projecting a spring garden because he can have no shrub-bordered lawn and no costly rock-work. One of the most interesting collections of spring flowers with which we are acquainted is in a city lot. It is interesting because its collector is a specialist who takes pains to find the choice species of Tulips, the most interesting forms of Snowdrops, Squills and Daffodils, and other early flowers; and because he cares for his own garden and has become an expert and an authority in spring flowering plants and their cultivation. When one has scarcely a square rod of ground there is room along the southern line of the house-foundation for many an early flower which needs its protection, and it must be a scanty lot indeed which will not furnish room for some clumps of the Poet's Narcissus. Novices should remember that the plants which flower next spring will have made every preparation to bloom the season before, and therefore the sooner herbaceous plants are in their places the better, while the bulbs will, as a rule, show better bloom if they are in the ground in early autumn. Those who are not novices will need none of these reminders, but to them we suggest the spring garden as a fascinating field of special study; and there need be no fear that this field is too contracted for a serious student. It will furnish ample scope for the most patient investigation. It is to the men who devote themselves to a single family of plants like the Primula or Narcissus to whom we look for instruction, and while they are adding to the sum total of horticultural knowledge they will find in the study itself its own ample and satisfying reward.

It is a matter of rare occurrence that names of botanists, often associated in scientific language with the names of trees, gain any real foothold in popular language. Magnolia, a name which commemorates the scientific labors of Pierre Magnol, a French botanist of two centuries ago, is a conspicuous exception in this country, and our great evergreen Magnolia is only known to the people living in those parts of the southern states where it grows as "Magnolia." The name of David Douglas is occasionally associated in British Columbia with the Fir-tree which he discovered, but "Douglas Spruce" can hardly be said to have established itself very firmly or very generally yet in the language of the people of any part of western America. Cases are less rare where the names of scientific worthies, perpetuated in the names of plants other than trees, are in common use; but trees, which are usually of importance to man or sufficiently conspicuous to attract his attention, obtain naturally local vernacular names before science imposes others on them, and the common names once engrafted on a language, almost always hold their own among the people of the country where the trees are found. It was a matter, therefore, of much interest and some surprise to hear recently, in western Florida, the *Torreya taxifolia*, one of the rarest of all our trees, spoken of generally as the "Torrey-tree"; and to find that Stinking Cedar, the unattractive name by which this tree was first known to the inhabitants of western Florida, was gradually being replaced by that of one of the Nestors of American botany. The reason for this change is found perhaps in the fact that this tree, from its rarity, the interest attached to the geographical distribution of the small genus to which it belongs, and the reverence which his successors have always felt for the name of John Torrey, has several times been visited in its remote and isolated stations on the banks of the Appalachicola by men of science from distant parts of the country. When the people of the region, therefore, found that men of mature years and apparently in the enjoyment of all their faculties had journeyed thousands of miles merely to look at a tree which they had always considered as valuable only because it furnished indestructible material for fence posts, their own interest and curiosity became aroused; and therefore hearing these eccentric strangers talking always about Torrey and Torreya, the name has gradually become fixed, and now "Torrey-tree" may often be heard in at least two or three counties of west Florida.

SIR DIETRICH BRANDIS offers the advice about the care of our forests, which appears in another column. If the voice of any man speaking words of warning on this subject is worth listening to, it is the voice of Sir Dietrich, or, as he is, still, better known, Dr. Brandis. No one better realizes the evils which follow excessive forest-destruction, or the possibilities of forest-administration. He it was who planned and successfully executed the scheme of forest-administration for India, one of the triumphs certainly of modern administrative genius. Forest-administration in India was established in the face of immense local opposition without the assistance of trained or adequate subordinates of any sort, and under natural and social conditions of great difficulty. The government forests of India were thirty years ago in as great peril as our own western forests are now, and the methods by which our forests are to be saved are very similar probably to the methods which Brandis put into execution, and which, at the end of a comparatively few years, not only secured the permanency of the Indian forests, but made them yield a large and steadily increasing income. No man who has yet spoken of our forests has done so out of such full knowledge of forest-conditions almost identical with our own, or with such extended knowledge gained in actual forest-administration, conducted on a vast scale and carried on under conditions which, at the outset, must have seemed well nigh hopeless to him and his friends.

Some Old American Country-Seats.

VI.—Hyde Park.

IN the days of the Revolution, Dr. Samuel Bard was a leading physician of New York. He was a decided Tory in feeling, yet he was a friend of Washington, and when the war was over, instead of migrating, he retired to a country house by the Hudson. He purchased his lands of the famous "nine partners," and named his seat in honor of Sir Edward Hyde, one of the Colonial governors of New York.

Hyde Park is to-day the name of a station on the Hudson River Railroad, the first stop above Poughkeepsie. The traveler who alights here looks in vain for any village, and after following the one road a little way, he finds himself beside a foaming waterfall, and sees beyond the stream a wide-spread and apparently unoccupied country-side, composed of woods, grass-lands, hills and vales, which he rightly conjectures to be Hyde Park proper. If the public road be followed as it winds up the valley to its junction with the old Albany post-road at Hyde Park Corner, and then the post-road be taken northward, the main gate of the park will be reached; but the park may also be entered from the river-side below the waterfall in Crown Elbow Creek.

A bridge, which leads to a landing on the bank of the Hudson, here spans the creek, and a narrow road enters the park in very modest fashion just beyond the bridge. Beginning at this gate, a belt of woodland stretches northward for perhaps a mile along the bank of the river, occupying the summits of the little crags and knolls which here make the rocky shore, and enclosing many charming bits of rocky woodland scenery. Parallel with the river, and just east of the wood, lies a gently hollowed valley of smooth grass-land, beautifully fringed by the waving edge of the dense wood on the one hand, and on the other rising with concave lines to meet the sharply ascending curves of a high, steep and grassy bank, which, with the great trees near its summit, bounds the scene on the east.

The little road which enters by the bridge commands one or two views of this bank and the long, green glade at its foot, and then it turns to follow the windings of the stream which comes dashing down over rough ledges and under shadowy Hemlocks on the right. The valley narrows until there is only just room enough for the stream and the road; and here a footpath breaks off to the left, and taking a rapidly rising open ridge, plainly indicates its intention to gain the summit of the high bank with the great trees which was lately in view. The road continues up the winding glen, passing by several pretty waterfalls; and, bye and bye, where the valley broadens and the stream is held back by a low dam, it joins the main approach-road, which here bridges the creek on its way from the Albany highway to the house. The united roads next ascend by one easy zigzag to a broad plateau of grass-land, set with numerous and variously grouped and scattered trees of noble age and stature, between the trunks of which the house soon appears in the distance. (See the picture on page 226.) This level ground is both wide and long, and its strikingly simple, open and stately effect is greatly heightened by the fact that from every part of it is visible in the west, beyond and behind all the massive tree trunks, an indefinite expanse of blue distance. When the house is reached, by the road just described or by the footpath before mentioned, it is seen to stand close to the brink of the plateau; in other words, upon the verge of the irregular, mile-long grassy bank the visitor saw first from below. The sudden descent of this bank, and the character of the trees upon it—chiefly old Chestnuts and Oaks—are shown in the picture on page 227. Some of the largest trees lean outward from the bank, and most of them grip the ground with a vigor befitting veterans who have long wrestled with the gales.

The view from the bank near the house embraces perhaps ten miles up and down the mighty river, with the varied opposite bank, and the wooded promontories near Staatsburg; and, in the far distance, the blue ridges of the highlands below Newburgh, the dark outlines of the Shawangunks in the west, and the pale summits of the Catskills in the north. Foreground, middle distance and distance are presented here with sharp definition. This is a scene not surpassed on the upper Hudson, unless the better composition of the river view from Ellerslie should place that wonderful picture first.

As the illustrations show, the house at Hyde Park is of a somewhat stiff and cold type; but it is simple and dignified, and in this respect is well fitted to its imposing site. Its south and west sides meet the grass of the park, its east side is the entrance front, and to its north-east corner is attached an ample kitchen and laundry yard, reached by a special road from the Albany highway, which, abreast of the house, has

gained the level of the upland. The stables stand apart a little to the north, and the greenhouses, with an enclosed garden attached to them, lie in a similar position on the plateau to the south. Both are entirely surrounded by the open groves of the park.

According to Mr. Downing, André Parmentier, of Long Island—the first landscape-architect who practiced in America—arranged the roads, buildings and plantations of the estate, under the patronage of Dr. Hosack, who succeeded Dr. Bard as proprietor. No man ever undertook a more responsible service in the realm of taste applied to landscape, nor one in which it would have been easier to fail by spoiling what nature had so magnificently provided. What a contrast is his work to the usual practice of the modern amateur, who, being a cultivated gentleman, considers himself quite able to lay out his own place. With the help of a jobbing gardener, he too often first despoils the natural scene of much that makes its character and beauty, for the sake of introducing supposedly decorative elements such as strange trees and the short lived brilliancy of flower-beds. Montgomery Place and Hyde Park should teach us better. The soft and tranquil beauty of the gentle landscape of the first named, and the broad stateliness of the upland scenery of the second, must impress all sensitive minds as no splendor of embellishment can. Decorative gardening, as it is often introduced in modern country-seats—that is, in patches scattered here and there—would at once kill the effectiveness of these old seats. Their power over the mind and heart consists chiefly in the unity of the impression which they make. Their scenery is artificial in the sense that Nature, working alone, would never have produced it; but the art which has here “mended nature,” to use Shakespeare’s phrase, has worked with Nature and not against her. It has, by judicious thinning, helped Nature to grow great trees; it has spread wide carpets of green where Nature hinted she was willing grass should grow; it has in one place induced a screen of foliage to grow thickly, and in another place it has disclosed a hidden vision of blue distance; and so, while it has adapted Nature’s landscape to human use, it has also, as it were, concentrated and intensified the expression of each scene. “Almost all natural landscapes are redundant sources of more or less confused beauty, out of which the human instinct of invention can, by just choice, arrange, not a better treasure, but one infinitely more fitted to human sight and emotion, infinitely narrower, infinitely less lovely in detail, but having this great virtue, that there shall be nothing which does not contribute to the effect of the whole.” Montgomery Place and Hyde Park on the Hudson may serve as illustrations of these good words of Mr. Ruskin’s.

Two other excellencies of these old seats remain to be mentioned so that they may perhaps be imitated. Firstly, the roads and paths, instead of displaying themselves and their curves as if they were the chief elements of beauty in park-scenery, are rightly made subordinate and inconspicuous, as befits the mere instruments of convenience they really are. When they run straight across level country they are shaded by trees in rows; when they curve, as they do only for good reason, formality of planting instantly stops. They lead to their objective points with directness and without superfluous flourish. Secondly, the makers of these old seats were wise in their generation in that they chose sites for their houses where ample space was obtainable and where fine trees already existed. Prevailing custom places fine houses on lots of land much too small for them, and many a mansion, architecturally excellent, is foredoomed to rise in some bare field where it must stand naked during many years. And yet, New England, not to speak of other parts of the country, abounds in accessible park-sites, crying to be occupied, where, if there is no such mighty river as the Hudson, there is great variety of lake, hill and mountain scenery adorned by fine trees and woods.

Boston.

Charles Eliot.

The Art of Gardening.—An Historical Sketch.

XX.—The Mahometans in Spain and India.

THE Generalif,* a sort of summer-palace attached to the Alhambra, stands on another spur of the same mountain. The walk from one to the other may be traversed in about a quarter of an hour, and leads through a ravine luxuriantly overgrown with Figs, Oaks, Laurels, Pistachios and Cystisus. The place, as Gautier described it fifty years ago,† wore the

aspect of a virgin forest; but it was once a carefully tended pleasure-ground, like the approach to the Alhambra on the other side, where natural effects had been simulated with consummate art. Much of the architectural beauty of the Generalif has perished, yet its gardens and water-works still delight the eye. Gautier says: “A marble bordered canal runs the whole length of the enclosure, rolling its rapid and abundant waters under arcades of foliage formed by massive and fantastically shaped evergreens. Orange-trees and Cypresses are planted on either hand. . . . The perspective is terminated by a gallery-portico with fountains and marble colonettes. . . . The canal makes a sharp bend and you penetrate into other enclosures ornamented with pieces of water and surrounded by walls. . . . In the middle of one of these basins opens, like an immense bouquet, a gigantic Oleander of incomparable beauty and vividness. When I saw it, it was an explosion of flowers, a veritable bouquet of vegetable fireworks. . . . The waters reach the garden by a sort of very steep inclined plane, edged with little walls, supporting channels of great hollowed tiles, through which the stream precipitates itself under the open sky. At each break in the descent the water rises in abundant jets from the middle of little basins, pushing its aigrettes of crystal into the thick foliage of the Oleanders which lock their branches above. The mountain ripples with water; . . . always one hears close by the murmur of some rivulet which is being led to feed a fountain or to moisten the roots of a tree.” Some writers say that this charming aqueduct was built as late as the time of Charles V.; but even if this is the case it represents a characteristically Moorish conception. The Oleander which so delighted Gautier is, according to others, not a single tree, but a massive group; its beauty, however, is always spoken of in terms as enthusiastic as Gautier’s own. It is, indeed, one of the “sights” of Granada; and still more famous is another feature in the gardens of the Generalif, a group of very large and ancient Cypresses—“Los Cupressos de la Reyna Sultana”—which have a traditional connection with one of the most sanguinary scenes in Spanish history. Every one has heard of the “massacre of the Abencerages,” a royal Moorish race; and it was precipitated by the fact, we are told, that in their trysting-place, beneath one of these huge Cypresses, a Christian king had surprised his wife with a Moorish prince.‡

Looking down from the gardens of the Generalif on one side “the hill disappears under an ocean of verdure,” while on the other there rises at a little distance a burnt, bare mountain throwing the more fertile scenes into incomparable relief.

In speaking of a convent not far away, Gautier says that the ancient Moorish garden had fallen into decay and wildness, but that he found an alley paved with white marble, flanked on each side by a long marble bench with a curved back, overarched with Oleanders of enormous size, and showing at the end of its long vista a magnificent panorama of the Sierra Nevada Mountains. This verdurous archway, with its marble *mastabah*, vividly recalls a description in the “Arabian Nights” of the approach to Haroun-al-Raschid’s “Garden of Delight” at Bagdad; and the fact is of interest as showing the essential identity of Saracenic ideas in all the widely separated lands where they found expression.

If the great palace at Zahra, near Cordova, built about the year 1000, still existed “we could afford to despise the Alhambra,”§ which represents a later and less admirable phase of Moorish art. The enclosing walls of this palace measured about 4,000 feet in one direction and 2,200 in the other. Like most Oriental buildings of the kind it consisted of a great number of apartments scattered about in gardens; and so rich were these gardens in marble kiosks, fountains and ornaments of every kind, as well as in plants and flowers, that “they may well have surpassed in cost and even in beauty” the buildings themselves, despite the 4,300 columns, the gilded roofs of cedar, the inlaid marble floors and the brilliant friezes of which the old historians tell.

Warlike tribes from central Asia early appeared in the west Asiatic provinces ruled by the Mahometan khalifs, Tartars coming first and Turks or Mongols later. They embraced the religion of the land and served for a time in its armies, but growing in numbers, they gradually gained one district after another for themselves. Before the middle of the thirteenth century pretty much all the ancient kingdom of Persia was in the hands of Ghengis Khan. His empire fell apart after his death, but a century later was consolidated by Tamerlane; and

*The name is properly *Ginut al arif*—“garden of the artist.” The place was created by the architect of the Alhambra, who afterward sold it to the king.

†“Voyage en Espagne.”

‡I venture to use the present tense in speaking of these trees, although I can find no recent account of their condition, and writers early in our century describe them as extremely old.

§Fergusson: “History of Architecture.”

then came new streams of Turkomans, until the history of the country almost disappears in a tangled web of conflict.

But when we follow these same invaders into the Indian peninsula, we find that, while apparently destroying Persia, they had absorbed the life-blood of its art. From the eighth to the thirteenth centuries there were constant Mahometan inroads into northern Hindustan. But the existing "Pathan dynasty" at Delhi was disturbed by the attacks of the great Mongol conquerors, Gengis and Tamerlane, and was succeeded by a Mongol dynasty, under whose most famous prince, Aureng-Zebe, Delhi rose to its highest pitch of splendor. Now, these Mongol rulers, whose dominion spread over a vast portion of northern India, were akin in blood not to the Persians or Arabs, but to the Chinese. Yet in India they used a thoroughly Saracenic art in their splendid buildings, and in their beautiful gardens, too. Not a trace of "Tartar" elements appears in their mosques, tombs or palaces; and the stately symmetry of their pleasure-grounds is utterly unlike anything that we find in the Chinese empire.

New York City.

M. G. Van Rensselaer.

New or Little Known Plants.

Paulownia Fortunei.

MR. HEMSLEY describes, in a recent issue of the *Gardeners' Chronicle*, a second species of *Paulownia*—*P. Fortunei*. This plant, it appears, was first collected by Fortune when he was in China, twenty or twenty-five years ago. His specimens, however, had no leaves and were confounded with *P. imperialis*.

"*Paulownia Fortunei* is readily distinguished from *P. imperialis* by its much elongated, heart-shaped, long-pointed leaves, glabrous and almost shining on the upper surface, with a very short and very dense whitish tomentum on the under surface. The flowers are longer and more curved, but I have no definite information of the color. The seed-vessel, too, is much larger than that of *P. imperialis*, as figured by Siebold and Zuccarini, but I have not seen a ripe one of the latter. So far as I know, *P. Fortunei* has only been observed, or at all events collected, in the two distant provinces of Kwangtung and Shantung, the actual localities being separated by about fifteen degrees of latitude. I have seen specimens of *P. imperialis* from Ningpo, which is situated on the coast about midway between the two places where *P. Fortunei* has been found, and Dr. Henry collected it in the central province of Hupeh, where, he notes, he observed it wild in various mountain localities. It is surprising that these two species should so long have been confused, though this probably would not have been the case had the common one proved a satisfactory ornamental tree in this country, and developed its full beauty. *P. Fortunei* produces its flowers early in the season, before or at the same time as the leaves; therefore we cannot hope that it will prove more suitable to our climate than *P. imperialis*."

In the neighborhood of this city *P. imperialis* is a familiar object, growing to a large size and adapting itself perfectly to our soil and climate. Further south, especially in some parts of Virginia and Carolina, it has become sparingly naturalized and is now found growing spontaneously among the indigenous forest-trees. It is probable, therefore, that the second species may thrive in some parts of the country at least.

Foreign Correspondence.

London Letter.

THE Daffodils may be classed with the Primrose, the Violet, the Wood Anemone and Hyacinth as typical English spring flowers. It is only within the last twenty years that the whole genus *Narcissus* has sprung into the very front rank as a popular garden plant, although Sir John Hill wrote in the year 1757 of the Poet's *Narcissus*: "The garden does not afford in its kind a prettier plant than this; nor do we know one that has been so early or so honorably mentioned by all kinds of writers." That the genus had attracted the attention of specialists long before what may be called the present revival of their culture is shown by Parkinson in his "*Paradisus Terrestis*," published in 1629, which contains figures and descriptions of nearly 100 kinds of *Narcissus*.

Although it is true that for a long time these plants were neglected by horticulturists generally, yet there have always been admirers sufficient to prevent their disappearance, and even to raise new kinds, so that few of those which Parkinson described have been lost. The attention of the present age has been directed to them by exhibitions, illustrated monographs and popular treatises upon their character and culture; probably also the fickle goddess Fashion has looked with favor upon them. Be the cause what it may, the Daffodils are now universal favorites, and where one grew them ten years ago a hundred grow them now.

The flowers rank second to none for decorative uses, and there are thousands of acres devoted to the cultivation of Daffodils for the supply of the London market alone. What flowers are best for the embellishment of rooms is a question which individual taste decides, but in my opinion there are no flowers, neither in summer nor autumn, nor yet amongst exotics, which excel the Daffodils as decorative flowers. They are abundant, they travel well, last a sufficient length of time; they are elegant, varied in color and in form, and many of them are deliciously fragrant.

If these plants are as popular in America as they are here all this is superfluous, but I am told that the passionate love of the English for Daffodils is peculiar to them. Messrs. Ware, of Tottenham, sent last year to the Paris Exhibition one of the finest collections of *Narcissus*-flowers ever shown, but, except *N. poeticus* and its varieties, it attracted little attention, and the exhibit was voted a failure!

The principal growers of these plants and the writers about them are Herbert Leeds, Backhouse, Nelson, Barr, De Graaf, Baker and Burbidge. Two of the very finest kinds—namely, Emperor and Empress—were chance seedlings raised by Mr. Backhouse. Leeds raised many beautiful crosses between the Trumpet and Poeticus sections, "which rival the choicest of all tropical Orchids in beauty, while at the same time they are perfectly hardy in our gardens." De Graaf has given us some magnificent seedlings, two of the very best being Beauty of Leiden and Madame de Graaf. In our opinion this last named is the most perfectly beautiful of all the Trumpet Daffodils. It is large, regular and elegant in form; the trumpet has an even, crisp, reflexed margin, whilst the color is soft, creamy white. Another sensational kind is Sir Watkin, the history of which is quite a pretty little romance. Its origin does not appear to be known. Its flower is of gigantic proportions, and its color is canary yellow with an orange-yellow trumpet.

In the face of the fact that there are no less than about five hundred named varieties of *Narcissus*, it is not easy to make a selection of a few which can be called the best of the lot. We have more names than distinctions; that is quite certain. The Royal Horticultural Society recognized this when they appointed, in 1886, a select committee to deal with the nomenclature of the genus. This committee still exists and finds plenty to do; more, in fact, than it can manage. Recently it has published a list of some fifty varieties of *Narcissus* which it considers are sufficiently well marked to deserve distinctive names. We had a great Conference and Exhibition of Daffodils in 1884, and another has just been held at Chiswick, extending over four days (from April 15th to 18th). The papers read at the Conference treated the botany, history, hybridization and crossing, the names and the cultivation of Daffodils of all kinds. With respect to the botany, that may be said to have been settled long ago by Mr. Baker, whose latest revision will be found in his recently published work on the *Amaryllidaceæ*. The history also has become an oft-told story. The only additional information yielded by the conference relates chiefly to matters of cultivation and improvement.

A paper on the cultivation of Daffodils for the supply of the London flower-market was read by Mr. James Walker, one of the most successful of those who grow flowers on a large scale. The gist of this excellent, practical paper was, in regard to soil, that a representative collection could not be grown well in the same soil. He planted a collection on a strong loam in 1881, and whilst some kinds increased fourfold in a year or two, others had died outright. He now divides his plants into two lots according as they prefer a heavy, well manured soil, or a lighter, less rich compost. He replants his bulbs every year, lifting them as soon as the leaves fade, drying and cleaning them, and replanting again in August and September, planting first those kinds which push new roots first. Mr. Walker insists on lifting, cleaning and replanting annually if first-rate results are expected. The kinds which he finds best for market purposes are:

TRUMPETS.—Emperor ("best of all"), Maximus, Golden Spur, Tenby and Spurius.

BICOLOR.—Empress, Horsfieldi, Grandis, Dean Herbert and J. B. M. Camm.

MOSCHATUS.—Of this white flowered group Mr. Walker did not speak highly, their flowers being too soft and not standing well enough for market purposes; he finds the following the best in this group, Mrs. Burbidge, Cernuus and Cernuus pulcher.

INCOMPARABILIS.—The best of all the many varieties included in this section is the giant Sir Watkin, and its nearest rival, Lady Watkin, of which Mr. Walker possesses the entire stock. Next to these he places Gloria Mundi and Princess Mary.

BARRI.—Maurice Vilmorin, General Murray, W. Ingram and Duchess of Westminster. The last named is large flowered, of excellent form and almost pure white.

BURBIDGEI.—The pick of this section Mr. Walker found in Constance, Falstaff, John Bain and Mary.

POETICUS.—All the forms in this section were, he said, of great value as market plants, whilst the best of them were Grandis, Recurvus and Poetarum. From the double-flowered kinds he selected Sulphureus (Codlings and Cream), Aurantius plenus (Butter and Eggs), and Telamonius plenus (Great Double Daffodil).

From this selection of kinds Mr. Walker is able to keep the market supplied with flowers from the end of January to the middle of May.

No one grows these flowers more perfectly or in greater numbers than Mr. Walker, who has close upon a hundred acres planted with them in his nursery near Petersham. His group of flowers at the exhibition was remarkable for its uniform excellence, not one of the hundred or so varieties it included being weak.

The principal exhibitor was of course Mr. Peter Barr, "King of Daffodils," as he is termed. Mr. Barr has done more than any one to bring Daffodils into popular favor, and he knows more about the cultivated forms than any other living man. He exhibited large groups of flowers of some two hundred named varieties and was awarded the gold medal of the Society. Kew sent flowers of one hundred and fifty named sorts. The great vineyard at Chiswick was filled with the flowers, and presented a most beautiful picture, such as had never been seen in any one place before.

Early Blooming Shrubs and Trees.

POSSIBLY on account of the unusual amount of snow on the mountain ranges west of the prairies our spring is late and but few ligneous plants are yet (April 25th) in bloom.

Of our indigenous shrubs under cultivation *Dirca palustris* (the Leather-wood) is first to expand its flowers, and our native Amelanchier (the Juneberry) follows closely and in advance of any of our varieties from Europe.

Of European and Asiatic plants some species of the *Prunus* family take the lead in earliness of bloom. A Manchurian Bird Cherry, *Prunus Padus*, expands its handsome foliage in advance of all our native and foreign species, and is now loaded with its really beautiful white racemes. As obtained from different parts of east Europe it runs into marked varieties. In beauty of tree and flowers a variety from Arel, in central Russia, excels all others I have yet seen.

Prunus virgata and *Prunus tomentosa* bloom with us at the same time, but are not equally hardy as to fruit-bud. While the tree itself is hardy enough, we rarely have the fine double flowers of the *P. virgata* in perfection. On the other hand, *P. tomentosa* is hardy in fruit-bud, and its blossoms will endure severe frosts.

The Siberian Apricot is now white with bloom, but it rarely fruits with us, as the flowers do not endure frosts or early spring storms as perfectly as do those of *P. tomentosa*, *P. Padus* and the Siberian Almond. In our climate the Siberian Almond (*Amygdalus Sibirica*) blooms with astonishing freedom and regularity. Three years ago it was loaded in early April with its pretty pink flowers during a frost that froze water an inch thick in a watering trough near it, yet the flowers were followed by a heavy crop of almonds, from which we grew hundreds of seedlings the next spring.

Of our collection of Barberries, *B. Thunbergii* and *B. Amurensis* come earliest into bloom, yet are not liable to be injured by frost or storms. *Forsythia suspensa* is now well laden with its yellow flowers, and, taken all in all, is the handsomest and best of its genus for our climate. Of the Elderberries, *Sambucus racemosa*, from Devil's Lake, Wisconsin, is in bloom with plants of this species from central Asia, while native individuals and those of west Europe are much later in flowering.

Of the Birches now in bloom, *Betula fruticosa* and *B. Gmelina* are the most interesting. The catkins are long, pendulous and peculiar, attracting much attention. Of the Willows now in flower, *Salix aurea*, of central Asia, is the most attractive. The long, yellow catkins, with the shining, half-developed foliage and bright yellow bark, give a pleasing expression not equaled by any Willow or Poplar in our collection. In the *Pyrus* family the wild Pear of the Altai Mountains is the most interesting. Its large, pure white flowers are in clusters at the points of growth, and form a fine contrast with the half formed silvery leaves. Worked at standard height on the common Pear of east Europe, *Pyrus salicifolia* forms one of our most desirable small trees of pendulous habit for the lawn. In a general way, I may add that eastern shrubs and trees of given species flower with us earlier than our indigenous plants. As an instance, *Prunus serotina*, from Massachusetts, blooms several days earlier than our native form of the species.

Agricultural College, Iowa.

J. L. Budd.

Notes After a Mild Winter.

THE unusual mildness of the past winter in the eastern part of America has again demonstrated some things regarding the plants of our gardens which have not infrequently come under the notice of horticulturists. The almost uniformly mild temperature (not touching zero at Boston) of the entire winter has been very favorable to many herbaceous plants which are ordinarily considered tender or but half-hardy. *Anemone Japonica*, with very slight protection, was quite uninjured, and the short stems of the rather tender St. John's Wort, known in England as the Rose of Sharon (*Hypericum calycinum*), with little protection, show very slight injury. It is among some of the woody plants that the effects of the mild winter are most noticeable. Most remarkable is the fact that our native trees and shrubs are rarely lured by warm mid-winter days into exposing their buds and blossoms to the frosts which suddenly and surely follow; but it is a common experience with many foreign species, natives of milder or otherwise dissimilar climates, that the flower-buds are pushed in mild weather beyond the limits of safety, and the result is that when spring comes the buds and half-opened flowers are dead. Here and there a few late buds escape and produce scattering flowers and perhaps fruit. In such cases one can imagine that the late blossoms developing into fruit might in the course of natural selection produce an acclimated race of the species; which having acquired the habit of late flowering, would not advance the buds too far until a comparatively safe season had arrived for expansion and development.

One lesson which has again forced itself on the attention of amateur planters is that soil and situation are often very important considerations affecting the vigor and endurance of some foreign plants. Even an exposed situation, where the soil is well drained, and not too rich, so that all parts of the plant become thoroughly ripened before autumn frosts, is apparently much more conducive to the hardiness of such trees and shrubs than when they are planted in rich, moist soil, where growth is continued until late in the season, and, in consequence, the plants are not fully matured and at rest before all activity is violently stopped by cold weather.

The Altheas (*Hibiscus Syriacus*) and the Weigelas are familiar plants which particularly illustrate the advantage of planting on a sloping bank or in a dry situation. In such positions they are usually as hardy as could be desired; but in rich, moist soils they are very liable to be killed to the ground. *Deutzia scabra* and its garden varieties and many species and varieties of Clematis are among the plants which are subject to severe injury in winter if grown in too wet and too highly cultivated situations. The buds of the tree Pæony (*P. Moutan*) are usually much advanced in the autumn, so that the leaves are plainly seen throughout the winter. These in some places have been killed, and it is noticeable that the injury is much less where the soil is warm and dry. The fragrant, early flowered, Asiatic Honeysuckles, *Lonicera Standishii* and *L. fragrantissima*, on low grounds lost most of their flower buds, and *Pyrus Japonica* sustained similar injuries except in much sheltered places. This plant, and the Honeysuckles to a lesser extent, are usually provided with some flower buds which are less advanced than the others, so that unless the stems of the plants are killed a few flowers are produced. The North American *Berberis* (*Mahonia*) *Aquifolium* is not a satisfactorily hardy plant about Boston; but here again a comparatively dry situation, added to a northern exposure with partial shade, gives the best result. Among plants which had many of their flower-buds killed

were the Forsythias, *Magnolia Lenné*, *M. stellata*, some Asiatic species of *Prunus*, and *Nuttallia cerasiformis* of the Pacific Coast. In all dry situations the Forsythias are as richly laden with blossoms as usual, but the buds were largely destroyed where the ground was wet, and similar effects were noted in comparing the early flowering small Magnolias.

On account of their precocious tendencies the pollen-bearing catkins of most of the foreign species of Hazels are usually destroyed before spring, and even the catkins of some of the exotic Willows shared the same fate during this mild winter. The frost did not penetrate far into the soil, and, coupled with the previous advantage of a damp summer, the past season was a very favorable one for the moisture-loving Rhododendrons and the Azaleas, and for the preservation of their flower-buds, although with few exceptions the buds of some extremely early flowering varieties were quite destroyed. With the protection usually given them, plants of *Calluna vulgaris* and allied Heaths appear to have suffered as severely this mild winter as they did in seasons with records of twenty below zero.

Arnold Arboretum.

J. G. Jack.

within the last ten years, and it is in bloom now. The racemes, five in number, are pendulous, two to three feet long, and bearing from fifteen to thirty flowers, each of which has a drooping pedicel six inches long, bearing a pair of large wing-like bracts four inches from its base, the flower being four inches across, and composed of four spreading sepals, five unequal petals, three of them large, and in the position usually occupied by the standard in the flower of an ordinary Legume. The stamens are united at the base, and form a long curved tube. The color of the whole flower, bracts, pedicel and all, is the richest vermilion or vivid scarlet, with blotches of rich lemon-yellow and a faint bluish tinge on the standard-like petals. In habit and foliage the plant resembles Brownea or Jonesia. The temperature supposed to be essential to this plant is from seventy to eighty degrees, with a bottom heat of ninety degrees, but the Kew plant is growing in a house devoted principally to Aroids and Tree-ferns, along with the largest of which it is planted out in an unheated but well-drained bed of soil. The temperature maintained in this house in winter is sixty-five degrees in severe weather, whilst in summer it ranges from seventy to eighty-five degrees. This is

Hyde Park: Entrance Front.—See page 222.

A Few Greenhouse Plants.

Amherstia nobilis.—It is now fifty years since this magnificent plant was introduced from India into England. Its fame had become known from a description by Dr. Wallich, who found it in 1827 in Martaban, growing along with *Fonesia Asoca*, another splendid-flowered leguminous tree. Writing of the Amherstia, Wallich said: "The largest of the two trees I found was forty feet high, with a girth of six feet near the base. Both were profusely ornamented with pendulous racemes of large vermilion-colored blossoms forming superb objects, unequaled in the flora of the East Indies, and, I presume, not surpassed in magnificence and elegance in any part of the world." Many futile attempts had been made to introduce this plant into English gardens before the Duke of Devonshire sent a collector specially for it, and succeeded in importing and establishing a plant in the famous Chatsworth Gardens. This plant is still alive. But the Duke was not the first to flower the Amherstia, a small plant in the collection of Lady Lawrence, at Ealing, flowering first in 1849. The first raceme that developed was sent to the Queen, and the second to Kew for figuring in the *Botanical Magazine*. A plant now in the Kew collection—originally, I believe, a cutting from the Ealing specimen—has produced a few flowers on several occasions

precisely what one keeps an ordinary stove at. Evidently, therefore, Amherstia may be grown and flowered in any house devoted to tropical plants. The Kew specimen is about ten feet high.

Aristolochia Goldieana.—In a genus remarkable for exceptional variety of form, size, color and odor, *A. Goldieana* is the most astonishing of all. It is the largest flowered of any known plant except the monster parasitic *Rafflesia Arnoldii*, which is peculiar to Sumatra; it is also very strong in form and very vile in odor. The tawny yellow or lurid purple color of the flowers and the possession of a strong disagreeable odor appear to be characters peculiar to all very large flowered plants, except, perhaps, the Victoria. Thus in *Stapelia gigantea*, the large *Amorphophalli*, *Godwinia gigas* and this *Aristolochia* we have these characters, namely, purple-brown and yellow, and an odor more powerful than pleasant. *A. Goldieana* was introduced into Britain in 1867, when a plant was received in Glasgow from the Rev. W. C. Thomson, a missionary in Old Calabar, who found it in flower "growing in a dry situation and surrounded with bush." This plant flowered in the Glasgow botanic gardens, and was figured in the *Botanical Magazine*, t. 5672. Probably all the plants of this species now in European collections are the progeny of this first introduced one. It has flowered several times within the last ten

years in botanical gardens, notably at Kew, where a plant of it is in bloom now. The root-stock of this species is rather woody and it bears thick fleshy roots not unlike those of Dahlias. The branches are annual, pushing into vigorous growth in early spring and perishing in the autumn. In winter no water is given. The Kew plant was repotted at the end of January into a ten-inch pot. It was then placed in the hottest and moistest house in a position close to the glass. The flower-buds, when the plant is strong enough to flower, are produced at the base of the new growth and they show almost as soon as growth begins. They develop very rapidly and when expanded they are in the form of the Dutchman's Pipe (*A. Siphon*), twenty-eight inches long from the base to the apex of the limb, with a constriction and sudden bend at about a foot from the base. From this bend the tube gradually widens upward until at the mouth it is sixteen inches across and is large enough to almost completely hide a man's head if put on as a hat. The three lobes are defined by three tails about three inches long. The color of the lower half of the flower is yellowish green, the upper half dull yellow ribbed and

sub-horizontal branches and pendent, axillary flowers, each on a stalk three inches long, and in form, substance and color not unlike the flowers of the pretty *Clematis coccinea*; in other words, the flowers are fleshy, arceolate, over an inch broad, and of the brightest crimson color. W.

Kew.

Notes on American Plants.

SEVERAL of the Dog's-tooth Violets (*Erythroniums*) are now in flower, but by far the most charming species we have seen is *E. Hendersoni*, which was described and figured in GARDEN AND FOREST, vol. i., page 317. The flowers of this plant have colors as rich and delicate as those of the Calypso. Of course there is nothing fantastic in their shape, as is the case with the Calypso, but in their way they are quite as pretty. The plants seem to be healthy in this climate. Ours were protected during winter with a covering of leaves, but we think that if the bulbs are set six or eight inches below the surface they would be perfectly hardy. Another interesting species from Oregon was sent us under the name of *E. Howellii*.

Hyde Park: River Front.—See page 222.

veined with purple on the outside, the inside being dull orange-yellow marbled with purple.

It is difficult to convey a correct idea of the plant by means of a description, but when seen it cannot fail to astonish even those who are well acquainted with plants. For botanical collections it is a splendid subject, and even in private gardens it is worth growing, the unpleasantness of its odor being more than counterbalanced by its wondrous size and form. It is easily cultivated, the only time when it requires extra care being for about a week when the buds are very small, as at this time the slightest check causes them to fall, when all chance of flowers for that year is gone.

Crinodendron Hookerianum.—Although a native of the American continent (Chili), and an old introduction into English gardens, I venture to recommend this beautiful-flowered greenhouse shrub to the notice of your readers as a plant worth the attention of every one who delights in distinct, elegant, bright-colored flowers. Veitch introduced it into England many years ago, and tried to grow it outside, but failed. *The Garden* published a colored plate of it about ten years ago, but still it remains a rarity in cultivation. A plant now flowering at Kew is one of the prettiest little objects. Imagine a *Vaccinium*-like plant, eighteen inches high, with

This has smaller, light cream colored flowers, slightly tinged with red, with a yellow centre. Both species thrive in a loamy soil in open sunlight.

One of the most interesting Trilliums at this time of spring is the *T. sessile*. Not on account of its flowers, for they have not yet opened, but for its three large spotted green leaves. It seems to give the finest display of foliage of any of this genus. A bed of this species planted last August is now in full leaf, a solid mass of the deep green. Each plant has three leaves in a whorl, and on the finest specimens each leaf is fully three inches wide.

Erigenia bulbosa (Harbinger of Spring), now in flower, is a small and dainty little plant, seldom more than five inches high, with a tuberous root. Its flowers are in a compound umbel, small and white. It seems to like the shade, or at least to be slightly shaded.

Synthyris reniformis, from Oregon, is an early flowering plant. Its blue flowers are borne in a dense spike about an inch long by half an inch in diameter. The reniform leaf is notched around its entire margin. The plant grows only a few inches high and is quite interesting, not only on account of earliness, but for its foliage and flowers.

Corydalis aurea, a not uncommon biennial, is a valuable plant for cultivation. It forms large clumps or masses of its

fine pale green or glaucous foliage, four to six inches high, and often more than a foot wide. At this time of spring, half hidden among its foliage, may be seen its pretty golden yellow flowers. These continue to appear until past midsummer. There are few of our native plants which, when brought to their highest state of development, are more attractive. A well drained loamy soil and open sunlight are what it needs.

Trollius laxus (Spreading Globe-flower) is an inhabitant of dark, shaded swamps. Its pale yellow flowers are about an inch wide, and come in early spring before many plants appear above ground. This earliness makes it interesting, for at this season a plant might attract us that would not do so a month later. It needs a moist, shaded situation.

Shortia galicifolia, now in flower, is a plant that would interest any one even if its history were unknown. The foliage is as fresh now as at any time, and the flowers, which are nearly white, or of a slightly creamy shade, are delicate and pretty, half an inch wide. The plant seems to prefer shade, or to be partly shaded. A fine, loamy soil suits it, and it is not difficult to grow.

Hardy Plants for Cut Flowers.—III.

MOST gardens possess a sheltered corner that is well drained and warm in winter, and such a position should be utilized to plant a bed of *Alstroemerias*. These beautiful plants are natives of South America, and belong to the *Amoryllidaceæ*, but do not receive the share of popular attention which they deserve. They flower without intermission for several months when well established and left undisturbed. We have tried three kinds—namely, *A. aurantiaca*, with bright orange flowers; *A. Chilensis*, with flowers of various shades of white, pink and yellow; *A. Peruviana*, with crimson and green-tipped flowers. *Alstroemerias* have thick, fleshy, tuberous roots, which are produced from a creeping rhizome, and these penetrate deep into the soil in search of nutriment and are usually secure from frost in mild winters, but in severe seasons it is best to place some dry non-conducting material over the plants after they have died down. The flowers of *Alstroemerias* are very showy, and are produced in terminal umbels, and last long when cut or on the plants.

Of *Anthericum Liliastrum* there has recently been introduced a variety Major, which is the best of all *Anthericums*. It is an early summer plant, and dies down after flowering as the Oriental Poppy does, to reappear early in spring. The flowers are pure white, more than an inch across, borne on stout, erect stems, and in every way adapted for house decoration. The plant is often known as St. Bruno's Lily, and is perfectly hardy.

The graceful habit of *Aquilegias*, the length of time they last in bloom and their hardness are all strong points in their favor; it is a pity they are not more durable when cut; but their profusion compensates for this in a measure, and certainly a garden of hardy flowers is not complete without the Columbines. It is well known how prone *Aquilegias* are to mix, but we have long kept three of the best native species true by gathering the first seed to ripen and cutting off the last flowers of *A. Canadensis*, *A. cerulea* and *A. chrysantha*, which flower in the order named. We shall have to adopt some other plan in the future, owing to the introduction of some twenty aliens. A word should be said for the Munstead Giant, a fine, pure white strain of the old *A. vulgaris*, the best white variety for cutting, owing to the stout, erect stems, which are two to three feet high.

The *Spiræas* deserve notice, for all are useful, though some more so than others; *S. astilboides* is one of the best, and is of recent introduction. It has dense spikes of white flowers similar to those of *Astilbe Japonica*, but it is quite distinct and taller in habit. It is pleasant to record that what was once almost a craze for *Spiræa palmata* is dying a natural death in favor of *S. lobata*, a native plant, known as Queen of the Prairies, which is quite as beautiful as the Japan plant, with fragrant flowers, and with a constitution that will ensure its thriftiness in any position. The double flowered form of *S. filipendula* is useful also, and is much more durable than the single variety.

It is rather surprising that people plant year after year seeds of the annual Candytuft when they could plant a perennial species and always have something green to rest their eyes upon, for all perennial Candytufts are evergreen. *Iberis sempervirens* is now a mass of snowy blossoms; *I. Garreuxiana* comes next, and then *I. corrafolia*, the largest flowered kind, after which *I. sempervirens* commences to flower again, which it will do sparingly until fall. *I. Gibraltaria* has handsome foliage and flowers, but, unfortunately, it is not hardy here,

though it is valuable for cutting when protected in winter. These hardy kinds of *Iberis* succeed best under the let-alone system, for when once planted they do not care to be disturbed, and soon form dense masses of foliage.

Orchard Experiences.—IV.

HOW to set out Apple-trees has been a subject of discussion for a great many years, and yet many who have written upon it have failed to lay down definite principles of work, or to go into details in a practically instructive way. It has been shrewdly said that a physician is worth more to his patients for what he forbids than for what he prescribes. Very much the same might be said of our horticultural teachers. There are many superstitions about tree-planting that are hurtful in themselves, or because they divert attention from things essential. Some planters are very particular that the young tree should be set exactly as it stood in the nursery, as regards the points of the compass. Others have a notion that the roots must be kept near the surface, and they try to insure this by placing a flat stone in the bottom of the hole. Many beliefs of this kind might be quoted, all of little or no importance, and usually founded upon tradition or on the practice of men really expert but full of "notions."

The first essential is to have healthy trees, with a good supply of healthy and unmangled roots. The next is a proper place, properly prepared, in which to set them out. Hard-pan land, or land underlaid with ledge within six feet of the surface, is fatal to success. One of the finest young orchards I ever saw was set out over rock not more than five feet from the surface. It grew thriftily, but had hardly come into full bearing when a summer of unusual drought almost entirely destroyed it.

Not only are healthy trees, properly taken up, essential, but the selection of varieties is no less so. For a family orchard of small size fancy may be allowed to guide, but a commercial orchard must be selected with a single eye to the marketableness of its crop. Standard market sorts are what the commercial grower must have. The soil has to be considered, because some valuable sorts are grown to perfection only on certain soils. The Yellow Bellflower is worthless almost everywhere except near the banks of rivers, like the Kennebec, the Connecticut and the Hudson. The Roxbury Russet requires, for its full perfection, a soil charged strongly with iron. When this variety is set in rows running out from a ferruginous soil to one of different quality, its fruit immediately shows the change, being there far inferior in size, and defective in the chief merit of this profitable variety, its keeping quality.

The holes in which trees are to be set must be large enough to take in the full length of the roots, and they need not be larger on any land desirable for an orchard, which should be naturally or artificially well drained. On a well grown tree the roots are commonly more or less in whorls, one above another; and these should be spread out separately, beginning at the bottom. Every root must slant downward to its tip, which should be smoothed with an undercut where bruised by the spade in digging. The hole ought to be gauged as to depth, so as to leave the tree, when set, not more than an inch deeper than it was in the nursery; and the earth should be carefully and firmly compacted about every root to its end. Trees thus carefully and firmly set require no watering, and the use of water in setting is objectionable, as interfering with the proper compacting of the soil by the hands. The feet should be used for this purpose only after all the roots have been placed and covered; and in treading remember to keep the toes pointed directly toward the stem of the tree—otherwise roots will be broken, and sometimes torn off.

Staking is necessary only when the trees are tall, with thick heads; and these trees are not so good as smaller and younger ones, which need no stakes. Mulching, however, is of great service. A good mulch will double the rate of growth in a young orchard; and I have found it profitable to grow Beans in my young orchards in order to have the straw for mulching. Bean-straw will not be blown off by the wind, it decays slowly, and when decayed is a powerful fertilizer. If one begins with mulching, however, it must be continued as long as the orchard is kept under tillage, for it keeps the feeding roots of the trees quite near the surface. Another incidental advantage of a Bean-straw mulch is that it is not nearly as easily fired by accident, and if fired it burns slowly, and is easily extinguished by throwing earth upon it.

It is well known that many otherwise valuable varieties of the Apple have a tendency to suffer in the bark on the side

next the sun at its hottest—when a little past the meridian. The bark becomes hardened so as to interfere with its growth by compression, and sometimes it is killed outright. It has been advised to attach a slip of board to the trees on that side; but another way is to lean the tree in setting a little to the west of south, and also to encourage the growth of a few short branches low down on the same side. It is, of course, better to select varieties not so sensitive to the sun's action, or to use such sorts for stocks, to be top-worked. It is well to know and remember points like these, for success with an orchard requires a wide and various knowledge of all the needs and peculiarities of the fruits we want to grow. Probably the larger part of all the orchards planted fail of profit because their proprietors have not an adequate knowledge of the minor details which are essential to successful management.

Seasonable Hints.—Many vegetables which are highly esteemed in Europe are comparatively unknown in American gardens, partly because they are not so easily cultivated in our climate, but mainly because they have not been more widely tried. Globe Artichokes, Sea Kale, Cardoon, Endive, Feticus, Celeriac and such herbs as Tarragon and Borage would make welcome additions to the supplies of many a country home where now they are never seen. Seeds of the Globe Artichoke may still be sown, although this should have been done a little earlier. The young plants should be thinned out so as to give room for full development, and should be transplanted the following spring to permanent beds, in rows three feet apart and three feet apart in the rows. It would be better now to secure a supply of young plants and thereby save a year. In any event, they will not bear much the first season, but afterward they will produce a fine crop for years, although it is better to renew the plants every two or three years. They need a covering of coarse litter in the winter, as they are rather tender, and they should be set in a comparatively dry spot, as they are liable to rot from undue moisture. In June they begin to produce flower-heads, which should be gathered before they open, and when properly served will be found a great delicacy. Seeds of Cardoon may be now sown very thinly in rows three feet apart, and thinned later to eighteen inches between the plants. With ordinary cultivation the leaves can be tied up by the latter part of August, to promote a perpendicular growth, and then they should be earthed like Celery. The plants can be preserved for winter by trenching as for Celery, and they make fine flavoring for soups and salads. Endive is extensively grown by German cultivators, but is rarely seen in the gardens of amateurs. The seeds may be sown any time before July 15th, and the plants should be transplanted into beds about one foot apart each way. The simplest way of blanching them is to set boards along the rows when they are about half grown. The curled varieties make ornamental garnishing for various dishes and the broad-leaved variety is highly esteemed as a salad. The seeds of Celeriac should be sown at once, and as soon as of sufficient size, the plants should be set in rows eighteen inches apart, with six inches between the plants. They require slight earthing up, and by November will have formed bulbs like a small turnip, which is the edible part of the plant. About this time they should be dug up, and placed entire in shallow trenches, with but a small portion of the top appearing above the surface, and over this straw may be laid as cold weather sets in. The sliced roots make an admirable salad, and when grated dry, are useful for flavoring the finest soups. Plants of Tarragon should be secured at once and set in a sheltered situation. The young leaves are not only useful for flavoring in cooking, but when placed in vinegar they make a palatable and appetizing condiment. The blue flowers of Borage are not only ornamental, but they are much sought by bees for the abundant nectar they yield, while the aromatic leaves are particularly valuable as flavoring for salads, cooling drinks and light wines. The seeds may be sown now, and transplanted into rows eighteen inches apart and twelve inches apart in the row.

P. O.

Magnolia Kobus.—It has been said of this *Magnolia* that it does not flower until it reaches a large size. At any rate, the behavior of a large specimen here warrants the belief that it is most unsatisfactory in its flowering. It is one of the finest specimens in this neighborhood, being fifteen feet high and sixteen feet broad at the base, and fully developed on every side. It has been growing in its present position twelve years. Until three years ago I never noticed a flower on it. It then had two. The next year it had the same number; last year, four or five; this year, one. The white flowers come before

the leaves, but they are small and are not sweet-scented. As a large, finely formed shrub it is unexcelled, but sadly disappointing in its flowers. It is often called *Magnolia Thurberei* in American gardens.

Fothergilla alnifolia.—This shrub is rarely seen in collections, but it is valuable for its beauty at this time of the year. It forms a bushy shrub, with Alder-like, small leaves. Early in the season, before its leaves expand, it is clothed with heads of white flowers. They are clustered together in a dense spike, not unlike a small bottle brush. It is so distinct and pretty that it should be better known.

Corylopsis spicata.—This is another good thing now in flower, but a new one, comparatively. It also flowers before the leaves appear. The pendulous racemes of yellow flowers on the hazel-like stems give it a character unlike any other shrub. It will be valued as one of the first of shrubs to flower in the spring, and because of its thriving in any ordinary situation.

Forestry in North America.—I.

A Manual of Forestry. By William Schlich, Ph.D. Vol. I. London: Bradbury, Agnew & Co., 1889.

It may be doubted whether this book will find many readers in the United States at present. The forest question at this distance seems as hopeless as ever. We read of forest-fires which destroy immense areas of magnificent woods, and the wholesale cutting of timber. Laws, it is true, have in some states been enacted to prevent the destruction of forests by fire, but in most instances they have remained a dead letter. The Federal Government, as well as some of the states, own extensive areas of forest-land, but these areas are diminishing rapidly by encroachments, and timber speculators find means to cut and lay waste the public forests.

Excellent treatises have been published to show that, if the present waste is continued, the difficulties will be serious, that in the drier districts, if the forest on the hills is destroyed, irrigation will be impossible and agriculture will suffer. Eloquent speeches on the forest-question are delivered at the meetings of the American Forest Congress and at local forestry associations. The practical effect of all these efforts has hitherto been insignificant. The matter seems perfectly hopeless and those who work the forests at present are not likely to be influenced by Dr. Schlich's Manual.

And yet the matter is not hopeless. Facts are stronger than arguments, and the facts are on the side of those who urge that forest-operations must be conducted on a methodical plan. What, then, is the essence of good forest-management? Simply this, that forests shall be treated in such a manner that they shall furnish, not huge masses of timber all at once, but a steady, and, if possible, increasing yield every year. The growing stock of trees, which is the accumulated wealth of centuries, must not be destroyed, but must be made to reproduce itself continuously, and to yield interest in the shape of annual cuttings.

Other countries have been in the same position in which North America finds itself at the present time. In other countries, also, there has been thoughtless destruction of accumulated forest-wealth. It has given way to a methodical system of working, which, in the long run, has been found to be far more profitable than the old system of wholesale cutting. When in British India measures were taken in 1856 to assert and to enforce the rights of the state in the Teak-forests of Pegu, and to substitute a regular system of management for the old practice of cutting down everything that was salable, the timber traders and other merchants of Rangoon raised an outcry of indignation. What they demanded was permission to cut whatever suited them. Teak-timber at that time commanded a high price, the merchants offered to pay liberally for permission to cut, and they argued that it was better to accept the revenue that would thus be realized, than to attempt the hopeless task of making the forests produce a permanent annual yield of timber. Iron, they added, would take the place of wood in ship-building, the demand for Teak would diminish, and ere long it would be a drug in the market. A brisk timber trade during a series of years, while Teak still commanded a high price, would greatly stimulate the development of Rangoon, while the growth of that town would be impeded by the refusal to comply with their demands.

Such were the arguments of those who opposed the adoption of a methodical system in working the Pegu forests. Large and important interests were at stake and their arguments seemed unanswerable. The forests were the

property of the state and it rested with the Government to say what was to be done. The influence of the mercantile community was great, and for a time their arguments prevailed with the Government at Calcutta. Orders were issued to open the forests to private enterprise. Fortunately these orders admitted of delay, and after a time wiser counsels carried the day. In this manner has it been possible to carry out the scheme of working the Teak-forests of Pegu upon a systematic plan.

The result has been favorable beyond all expectation. Ever since 1856 the Teak-forests of Pegu have yielded a large annual out-turn of timber, increasing in quantity as well as improving in quality, and at the same time the demand for Teak-timber has risen steadily. This has stimulated the export from other ports. The quantity of Teak-timber brought into the market from all sources has increased enormously since 1856, and yet, owing to the increased demand, prices have remained high. The trade has benefited largely and the growth of Rangoon has been rapid and steady beyond all expectation. In 1856 the Teak-forests of Pegu were not closed. The full quantity of timber, which their condition justified, was cut and exported annually, but the work was arranged in such a manner that their productive powers were not impaired and that the capital value of these estates was increased instead of being diminished. Lastly, Government has derived a large and steadily increasing annual income from this source. This was a point of vital importance. A new scheme had been carried out in the teeth of great and powerful opposition, and there was good reason to apprehend that unless revenue was produced the new scheme would not be permitted to continue.

As it was, the experience gained in Pegu acted as a powerful stimulus to systematic forest-management in all provinces of the large British-Indian Empire. Here, as in Pegu, the duty of taking action devolved upon the state, and the government is now reaping the reward of these measures in the shape of a large and steadily increasing annual forest-revenue and a large and steadily growing capital value of its forest-domains. The success attained in the management of the Government forests has induced native princes and large landed proprietors to follow suit and to manage their woodlands in a similar manner.

If it once comes to be understood in America that good forest-management does not mean the closing of the forests, but working them with moderation and on a definite plan, that forest thus managed is a permanent and valuable investment, then, not the state only, but private proprietors also, will commence managing their woodlands in a methodical manner, instead of allowing them to be ruined.
